George C. Marshall Space Flight Center
Marshall Space Flight Center, Alabama 35812**

FOREWORD

This report was prepared by Wyle Laboratories, Scientific Services & Systems Group, for the George C. Marshall Space Flight Center, National Aeronautics and Space Administration. The work was performed under contract NAS8-38156, entitled "Data Analysis and Diagnostic Evaluation of Space Shuttle Main Engine Dynamic Measurements" over the time period from June 1989 through October 1993.

The investigation was carried out by the Systems Analysis Department, with Mr. T. Coffin serving as Program Manager. Mr. W. L. Swanson was Project Engineer for SSME data analysis and bearing element dynamic modeling, in particular. Dr. J. Jong was responsible for the development of diagnostic signal processing techniques, and application of these methods to SSME anomaly investigations. In addition, he conducted several seminars at MSFC concerning advanced signal processing methods and applications. This report documents the diagnostic analysis effort performed under the above contract. A secondary objective of the authors was to provide an overview of the SSME diagnostic evaluation process, and the computational tools available to support this task.

Messrs. J. E. McBride and C. P. Jones, MSFC/ED23, provided valuable guidance through coordination of test evaluation activities and definition of task requirements and priorities. Mr. J. H. Jones, MSFC/ED33, provided valuable technical advice and encouragement to the diagnostic technique development effort.

EXECUTIVE SUMMARY

The Marshall Space Flight Center is responsible for the development and management of advanced launch vehicle propulsion systems, including the Space Shuttle Main Engine (SSME), which is presently operational, and the Alternate Turbopump Development (ATD) concept presently under test. Advanced turbomachinery bearing, blade material, and instrumentation concepts are also under evaluation at the MSFC Technology Test Bed (TTB). The SSMEs provide high performance within stringent constraints on size, weight, and reliability. Based on operational experience, continuous design improvement is in progress to enhance system durability and reliability. Specialized data analysis and interpretation was provided by Wyle Laboratories in support of SSME and advanced propulsion system diagnostic evaluations, under NASA Contract NAS8-38156.

Under the extreme temperature, pressure, and dynamic load environments sustained during operation, engine systems and components, such as pumps, turbines, and associated hardware, are subjected to severe pressure oscillations and damaging mechanical vibrations. Through extensive data evaluation and analytical effort, turbomachinery and related component vibrations have been implicated as a primary source of equipment degradation and even several catastrophic failures. Measured vibration signatures have varied from stationary random in nature to highly transient functions and even pure tones in some cases.

Most mechanical failures are preceded by growing tolerances, imbalance, bearing element wear and the like, which may manifest themselves through subtle changes in the waveform observed by dynamic measurements. Diagnostic vibration analysis is based on observing and discriminating between measurable vibration patterns that occur as a result of nominal system operation and those associated with component degradation. The techniques are analytical, but their application is necessarily empirical, relying heavily on a data base of engine measurements permitting correlation between derived signature characteristics and observed mechanical condition. The diagnostic evaluation of complex vibration signatures requires the use of sophisticated statistical/signal processing techniques and highly experienced analysts for efficient interpretation.

Comprehensive evaluation of the dynamic measurements obtained from test and flight operations is necessary to provide timely assessment of the vibrational characteristics indicating the operational status of the turbomachinery and other critical engine components. Efficient

performance of this effort is critical due to the significant impact of dynamic evaluation results on ground test and launch schedules and requires direct familiarity with SSME and derivative systems, test data acquisition, and diagnostic software.

The basic objectives of this contract were to perform detailed analysis and evaluation of dynamic data obtained during SSME test and flight operations, including analytical/statistical assessment of component dynamic performance, and to continue the development and implementation of analytical/statistical models to effectively define nominal component dynamic characteristics, detect anomalous behavior, and assess machinery operational condition. This study was to provide timely assessment of engine component operational status, identify probable causes of malfunction, and define feasible engineering solutions. The work was performed under three broad tasks which are summarized as follows.

TASK I: Analysis, Evaluation, and Documentation of SSME Dynamic Test Results

Under this task, Wyle performed analysis, evaluation, and documentation of SSME dynamic test results. This task represented the mainstream of the contract effort and included data verification, analysis, evaluation, and documentation for each SSME ground test and, additionally, for SSV flight measurements. Results were provided immediately and informally for SSME Program Management Review. Over the course of this study, 456 SSME hot firings, including 372 single engine tests and 28 STS flights were evaluated. Of the single engine tests, 38 included instrumented ATD turbopump configurations. Additional data analysis was provided for component tests at the MSFC Technology Test Bed, water flow facility and various contractor locations.

TASK II: Data Base and Analytical Model Development and Application

The Automated Data Base and associated statistical models of the SSME component dynamic response were updated and applied to generate characterizing profiles of observed parameter ranges, distributions, etc. under nominal and abnormal operating conditions at all power levels. Statistical and graphical routines were incorporated to aid in data evaluation and interpretation.

TASK III: Development and Application of Vibration Signature Analysis Techniques

Signature analysis techniques were developed, updated, and applied for detailed SSME diagnostic evaluation. Under this phase, Wyle developed a number of advanced time domain and spectral evaluation algorithms and implemented them on the OISPS.

The above tasks are seen to be intimately related since promising fault detection schemes were immediately integrated into the SSME evaluation process. These efforts were directed to a number of specific SSME engineering applications, including:

- Analysis, evaluation, and documentation of SSME test/flight measurements.
- Support of abnormal SSME operation or component failure investigations.
- Development of analytical/statistical models of component dynamic behavior and application to SSME component evaluations.
- Analysis, modeling, and simulation to refine test and flight vibration redlines and flight certification ("green-run") specifications.
- Data base development and implementation to support SSME data classification and evaluation.
- Development/implementation of advanced vibration signature analysis techniques for monitoring SSME operational condition and diagnostic assessment of component degradation.

This report provides an overview of study objectives and approaches applied by Wyle in the performance of Contract NAS8-38156. As a test/evaluation program, rigid, long term task planning was neither feasible nor desirable. On the contrary, most tasks performed under this contract were initiated on an ad hoc basis, motivated by observed or suspected SSME component failure modes. Continued coordination with the MSFC COTR was, therefore, maintained to revise task priorities based on SSME test results and Project Office requirements. Consistent with stringent SSME test and flight certification schedules, evaluation results were immediately provided the COTR in the form of presentations and informal data packages. To illustrate the diversity of tasks accomplished under this contract, some reports and presentations prepared by Wyle in support of propulsion system dynamic evaluations are summarized in Appendix A at the end of this report. Appendix B includes the course notes for a seminar series on Advanced Diagnostic Techniques, provided under this contract. A detailed chronology of these evaluations is given in the technical progress reports provided under this contract.

The primary purpose of this report is to document the work performed under NASA Contract NAS8-38156. A secondary objective of the authors was to provide an introductory overview of the data analysis/diagnostic evaluation process. In particular, the investigations discussed in Appendix A and the analytical techniques described in Appendix B should prove a valuable guide for orientation regarding data analysis procedures and the tools available for component diagnostic assessment.

- SECTION II

PROGRAM OVERVIEW AND SUMMARY OF TASKS

2.1 Introduction

The Marshall Space Flight Center is responsible for the development and management of advanced launch vehicle propulsion systems, including the Space Shuttle Main Engine (SSME), which is presently operational, and the Alternate Turbopump Development (ATD) concept presently under test. Advanced turbomachinery bearing, blade material, and instrumentation concepts are also under evaluation at the MSFC Technology Test Bed (TTB). The SSMEs provide high performance within stringent constraints on size, weight, and reliability. Based on operational experience, continuous design improvement is in progress to enhance system durability and reliability.

During development of the propulsion system for the Space Shuttle, the state-of-the-art in rocket engines has seen significant advances. The performance of such engine components as pumps, turbines, and bearings in the presence of high rotational and fluid velocities at high dynamic pressures has resulted in severe fluid pressure fluctuations and destructive vibrations. The character of these vibration signatures varies from random in nature to that of complex periodic functions and even pure tones in some cases. To quantify and analyze these complex signatures, in many cases, requires the utilization of sophisticated analysis techniques and highly experienced analysts for interpretation. Under NASA Contract NAS8-38156, Wyle Laboratories has provided specialized data analysis and interpretation in support of SSME diagnostic evaluations. This report summarizes the effort performed under that contract.

Under the severe temperature, pressure, and dynamic environments sustained during operation, engine systems and components have been subject to malfunction and failure. Over the past 17 years of SSME development, over 28 major component failures have occurred, causing extensive damage to engine hardware and test facilities, at considerable expense in cost and schedules. In addition, numerous off normal operations of a less severe nature have occurred, including turbine blade cracks and bearing element failure. Through extensive test and data evaluation effort, turbomachinery and related component vibrations have been implicated as the source of many high cycle fatigue problems and some catastrophic failures. These events underline the need for comprehensive evaluation of the dynamic measurements obtained from test and flight operations, to provide timely assessment of the vibrational characteristics indicating the operational status of turbomachinery and other critical engine components.

Efficient performance of this effort is critical due to the significant impact of dynamic evaluation results on ground test and launch schedules and requires direct familiarity with SSME and derivative systems, test data acquisition, and diagnostic software.

This section presents an overview of program objectives and task accomplishments. The Space Shuttle system is briefly described, with particular attention to SSME operational characteristics. Summarized also are some technical considerations in the analysis and evaluation of SSME dynamic data. SSME development/certification test procedures are briefly reviewed and a typical test data review cycle is summarized. Contract task requirements are reviewed, along with engineering approaches applied to their accomplishment. A summary of reports generated in the conduct of this contract is included at the end of this section, which illustrates the diversity of investigations performed. Analytical/statistical modeling studies, to characterize SSME component dynamic behavior, are included in the Appendix.

2.2 The Space Shuttle Vehicle System

The SSV is composed of the Orbiter, an External Tank (ET), which contains fuel for the Orbiter's three SSMEs, and two Solid Rocket Boosters (SRB). The Orbiter and SRBs are reusable; the ET is expended on each launch.

A Space Shuttle mission begins with installation of the mission payload into the Orbiter cargo bay. The SRBs and the SSMEs fire together at liftoff. The two SRBs are jettisoned after burnout—about 45 kilometers (28 miles) high—and recovered for reuse by means of a parachute recovery system. The SSMEs continue to burn until the Orbiter is just short of orbital velocity, at which time the engines are shut down and the ET jettisoned. During its return through the atmosphere, the tank will tumble, break up and be destroyed.

The orbital maneuvering system is used to attain the desired orbit and to make any subsequent maneuvers that may be needed during a mission. After orbital operations are completed, normally about seven days, deorbiting maneuvers are initiated. The Orbiter reenters the Earth's atmosphere at a high angle of attack. It then levels into horizontal flight at low altitude for an unpowered aircraft-type approach, landing at a speed of about 335 kilometers per hour (208 miles per hour).

2.3 The Space Shuttle Main Engines

The Orbiter vehicle main propulsion system consists of three SSMEs. The SSMEs are reusable, high-performance, liquid-propellant rocket engines with variable thrust. All three engines are

ignited on the ground at launch and operate for approximately 500 seconds total firing duration. Each engine operates at a mixture ratio (liquid oxygen/liquid hydrogen) of 6:1 and a chamber pressure of approximately 3000 psia to produce a sea-level thrust of 375,000 pounds and a vacuum thrust of 470,000 pounds. The engines are presently throttleable over a thrust range of 60 to 109 percent of the design thrust level. This provides a higher thrust level during liftoff and the initial ascent phase, and allows Orbiter acceleration to be limited to 3 g's during the final ascent phase. The engines are gimballed (± 10.5 degrees for pitch and ± 8.5 degrees yaw) to provide pitch, yaw, and roll control during the Orbiter boost phase.

Significant to meeting performance requirements is the use of a staged combustion power cycle coupled with high combustion chamber pressures. In the SSME-staged combustion cycle, the propellants are partially burned at high pressure and relatively low temperature in the preburners, then completely combusted at high temperature and pressure in the main chamber before expanding through the high-area-ratio nozzle. Hydrogen fuel is used to cool all combustion devices in contact with high-temperature combustion products. An electronic engine controller automatically performs checkout, start, mainstage, and engine shutdown functions. Major components of the SSME are illustrated in Figure 2-1. A more detailed view of the SSME power head is shown in Figure 2-2. This figure provides an indication of the complexity of the SSME turbomachinery. The propellant flow schematic, Figure 2-3, illustrates the staged combustion cycle discussed above.

2.4 SSME Development and Certification Testing

To validate system performance and ensure equipment reliability, the SSME and components have been and are presently undergoing extensive development and qualification tests. For example, testing of a candidate replacement (the A.T.D. unit) for the operational High Pressure Oxygen Turbopump, Figure 2-4, is in progress. The A.T.D., Figure 2-5, incorporates advanced manufacturing (forging/welding) techniques and alternate bearing/rotor technology. Testing of the engine and components is conducted at several NASA and contractor locations. Full scale engine test firings for development and flight acceptance are performed on single-engine test stands at Stennis Space Center, Bay St. Louis, Mississippi. In addition, propulsion system testing is in progress at the NASA Engine Technology Test Bed and gas/liquid flow facilities, Marshall Space Flight Center, Alabama.

FIGURE 2-5. ATD OXIDIZER TURBOPUMP

Testing is performed on a continuing basis. The length of a given test is dependent on specific test objectives and may run from several seconds to over 800 seconds. Tests are generally designed to satisfy multiple specific objectives, which fall into two broad categories: (1) Acceptance/certification firing of flight hardware and (2) Development testing directed toward design verification, performance, and reliability improvement. Test operations are controlled by a computer called the Command and Data Simulator (CADS) which communicates with the engine, displays vital measurements for on-line observation/control and initiates pre- and post-procedures.

Approximately 250 measurements are recorded on a given test, including wide band vibration, dynamic pressure and strain at critical engine locations. Some of these measurements are utilized on-line as emergency cut-off indicators and all are recorded on magnetic tape or stored digitally for subsequent analysis and evaluation. Limited SSME vibration measurements are recorded on magnetic tape during SSV flights for evaluation after orbiter landing. Figure 2-6 illustrates a schematic of the standard SSME ground test instrumentation. In addition to the above engine tests, dynamic data are also acquired from component testing at government and contractor facilities.

2.5 Data Analysis and Evaluation Considerations

2.5.1 Quick-Look Data Assessment

Acceleration measurements are obtained at fuel and oxidizer turbopump locations during all test firings, providing an extensive vibration data base representing various turbopump builds under widely differing operating conditions. Additional measurements are obtained on a test-specific basis, depending on performance, structural integrity, or rotor dynamic characteristics under evaluation. For example, test series have been performed with some 80 strain measurements to support engine nozzle and injector dynamic stress evaluations. Recent firings have also been conducted with internally instrumented turbopumps to define component dynamic load and signature characteristics. Figure 2-7 illustrates the standard SSME hot firing test profiles and associated mission phase/test objectives, indicating the wide range of engine operating conditions to be assessed. Thus, it is seen that the extent of the evaluation process varies widely from test to test, even though engine performance is nominal. In the event of anomalous performance or component malfunction, the extent of this process is increased significantly. Limited turbopump measurements are also obtained from the three SSMEs on each SSV flight. Data bandwidths available from SSV flight instrumentation differ from the wide-band capability used during ground testing, thus, the need for generating a data base of filtered ground test

measurements to permit direct comparison with flight results. Typical activities involved in an SSME test evaluation cycle are summarized as follows.

Data Evaluation and Documentation:

- Data verification and validation
- Events analysis
- Temporal and spectral correlation with operating profile, machine dynamic characteristics, and previous measurements
- Test/flight data summary, including conclusions concerning component condition and operability

Analytical/Statistical Modeling and Classification:

- Update statistical models characterizing normal and abnormal behavior
- Update SSME diagnostic data base and redlines
- Develop and apply computer programs to define SSME component dynamic behavior

Failure/Anomaly Investigation:

- Time/event correlations with other test parameters/observations
- Temporal and spectral comparison with structural dynamic and statistical models and associated failure modes
- Detail signal analysis with fault detection/identification algorithms
- Evaluation and recommendations of probable cause/effect scenarios, and means of resolution

It should be noted that the above evaluations must be performed under extremely limited time constraints consistent with test and flight schedules. Also, the extent of a given evaluation will vary significantly, depending on the specific measurements acquired and whether or not observed engine operation is nominal.

2.5.2 SSME Data Base Application and Refinement

Efficient performance of the above evaluation relies strongly on historical data representing SSME component operating characteristics under varying conditions. Significant effort was directed to the development, modification, and application of MSFC Diagnostic and Statistical data base programs. These programs are used extensively in routine test evaluation and also in diagnostic investigations. The SSME diagnostic data base and software have greatly facilitated the generation of quick-look performance summaries and comparisons for input to the SSME data reviews conducted immediately after each test, as well as the maintenance and update of historic statistical profiles.

A number of sophisticated diagnostic algorithms have been integrated into the "Operator Interactive Signal Processing System (OISPS)," and are operational on the MSFC/Structures and Dynamics Laboratory computers. These include non-linear and non-stationary spectrum analysis, adaptive filtering, cavitation detection and other analytical methods applicable to specific SSME mechanical symptom detection and identification investigations. These techniques and their application are discussed in detail in Appendix A of this report. For quick-look data assessment, the (linear) power spectral density (PSD), 'Isoplot,' Topo Plot, and Root-Mean-Square (R.M.S.) time history of a measurement are the most basic and valuable computational tools. When viewed in the context of empirical statistical data representing SSME component measurements obtained under similar operating conditions, these analyses can provide a quick, qualitative indication of component "health" (from a dynamics standpoint) and signal any gross deviations from nominal operation.

The most fundamental "Signature" utilized to characterize an SSME vibration (acceleration, pressure, strain, etc.) measurement is the mean-square density spectrum, or power spectral density (PSD). Figure 2-8 illustrates a PSD from two high pressure fuel pump acceleration measurements obtained during constant operation at 109 percent power level. Pump shaft (synchronous) speed and related spectral peaks are clearly indicated, as well as an anomalous spike, requiring further investigation.

Interpretation of these results clearly requires knowledge of the mechanical system and reference to nominal data base statistical values, as noted above. In addition to the PSD, these figures include descriptive information to aid in data identification and evaluation, including

- SSME Test Number
- Measurement Location
- Test Time of Analysis
- Engine Power Level (at time of analysis)
- A Summary of Predominant Spectral Peaks and Associated Frequencies
- Composite Vibration Level (RMS)
- Band-Pass Level (RMS) at the Synchronous Frequency
- Sample Size (No. of Averages) Used in the Analysis
- Spectral Resolution (Bandwidth) of the Analysis.

Figure 2-9 illustrates an isoplot of a strain gauge measurement representing 450 seconds during a hot-firing test and also a fuel pump acceleration measurement. The PSD provides a detailed 'snap-shot' of conditions over an interval of (usually) constant power operation. In contrast, the isoplot yields a more qualitative indication of amplitude/frequency trends over a complete hot-firing test or powered flight. These plots are particularly useful for detecting the time of any significant deviations in the vibration signature and correlation with engine operating parameters (power profile, programmed venting, etc.). To provide improved tracking of spectral trends, a method called "TOPO" (for Topographic Plot) was developed and programmed. The method uses a novel peak-identifying routine to pick out all meaningful peaks in each PSD and assign a "peakyness" parameter for each identified peak. Each peak is then plotted on a TOPO plot as a dot whose width is proportional to the "peakyness" parameter associated with the peak. Figure 2-9 includes an example of bearing test data during ramp-up. Four hundred PSD's are plotted in this figure, and the non-stationary and crossover behavior can be clearly visualized.

To generate quick-look analyses, the SSME Isospectral Data Base System has been applied extensively. With this system, spectra are extracted at the test site (typically, every 0.4 seconds) for each measurement throughout each test and stored. On command, the spectral data is telemetered to MSFC via satellite. Based on MSFC-developed software, these preprocessed data are then manipulated and printed to display isoplots, bandpass trends, engine speed, etc., on user command. In computing the above isoplot, a frequency band of 3 KHz to 5 KHz was selected and a spectrum plotted every 5 seconds. The displayed amplitude range is selectable, permitting clear representation of major spectral peaks or identification of low level spectral components. Interpretation obviously requires correlation with engine speed and other parameters. Figure 2-10 illustrates the root-mean-square acceleration time history composite and synchronous levels for two selected measurements. These time histories were synthesized from the stored isospectral data by integrating over the PSDs obtained at 0.4-second intervals during the test.

Figure 2-10 also illustrates a highly useful aid to data evaluation, developed under previous contract. Superimposed on the measurement time histories are characterizing statistical levels derived from analysis of extensive previous tests, representing nominal SSME operation. As far as these two condition indicators are concerned, brief inspection indicates a very smooth running machine. It should be noted that these 'overlay plots' represent a separate statistical analysis of each measurement, for each constant power level, extracted from the SSME vibration data base. Several diagnostic algorithms, to enhance data base application, have been incorporated in the menu driven system.

2.5.3 Diagnostic Methods and Applications

The hypercoherence method was extended to a time-domain filtering algorithm for the extraction of periodic vibration signals in noisy SSME data. The procedure is best illustrated by example. Figure 2-11a illustrates the orbit plot for two jointly periodic signals, each containing three harmonic components. Figure 2-11b represents the same plot when uncorrelated noise and independent, coincident periodic components have been added to each signal. This chaotic pattern is highly representative of hot firing data. Figures 2-11c and 2-11d are the recovered orbital diagrams by hypercoherence filtering and comb filtering, respectively. The superior performance of hypercoherence filtering is clearly indicated.

The Wide Band Demodulation (WBD) technique was applied to the detection of cavitation in turbopump systems. When cavitation occurs, the periodic shaft rotational components will amplitude modulate the wide-band noise generated from collapsing cavitation bubbles. This wide-band modulation will make the periodic component become undetectable in the raw PSD of its dynamic measurement signal. However, this special phenomenon provides a unique signature for cavitation detection and monitoring. By using the WBD technique, the hidden periodicity can be recovered from a wide-band high frequency noise signal. The resulting WBD PSD can better indicate cavitation condition changes as compared to an ordinary raw data PSD. The application of WBD to cavitation detection is illustrated in Figure 2-12. Figure 2-13 indicates several analytical approaches to perform the transformation. The WBD method has aided the identification of hidden periodicities in MSFC turbopump inducer flow test data and correctly indicated changes in the cavitation level during test.

A novel technique, the Modified Wigner Distribution (MWD) was developed for resolving time-frequency trends in highly non-stationary vibration data. Standard Fourier-based routines (e.g. FFT) imply the assumption of a stationary time series. However, turbomachinery operation includes highly nonstationary periods associated with engine startup, shutdown, and throttling. The Wigner Distribution (WD) is capable of high resolution estimates for nonstationary signals, but suffers from aliasing resulting in false peaks, for series with multiple spectral peaks. A demonstration of the MWD method in the evaluation of multiple components signals is shown in Figures 2-14, 2-15, and 2-16. Figure 2-14 shows the short-time FFT isoplot of a simulated signal composed of two sine waves. The frequencies and amplitudes of the discrete components are changing rapidly, and the corresponding spectral peaks are smeared. The WD spectrum for the same signal is shown in Figure 2-15. With the multicomponent signal, the WD introduces erroneous cross coupling component between the two simulated sine waves. This "phantom" peak train distorts the resulting time-frequency spectrum. Figure 2-16 is the corresponding

FIGURE 2-16. MWD ISOPLOT OF TWO MODULATED SINE WAVES

MWD spectrum for the SSME signal. As can be seen in the figure, an improved resolution is attained over that of the STFT, without unwanted cross coupling terms.

The SSME static firing and flight vibration data contains many frequency components that can be confused with incipient bearing deterioration signatures if not carefully analyzed. This can lead to rejection of turbopumps with good bearings and the extremely high cost associated with teardown, inspection, and recertification, not to mention the impact on schedules. In an effort to define the rotational frequencies and detect signature of ball bearings operating at high speeds from the geometrical bearing configuration, a number of analytical and computer simulation routines were developed and implemented. The ADORE (Advanced Dynamics of Rolling Element bearings) program has been extensively applied over the last two years. With this program, any arbitrary variation in bearing geometry (ball wear, etc.) or manufacturing tolerances, can be modeled and the influence of time varying operating condition on each bearing element calculated. The bearing elements include the inner and outer race, ball or roller, and the cage. For each rolling element the orbital position, velocity, relative angular position, spin/roll ratio and slip velocity are available for studying the vibration signature. This program has basically replaced the previously developed methods, which only considered the geometrical bearing configuration. Some of the imperfections, operational conditions and manufacturing tolerances investigated recently with the ADORE program include:

- Imperfections in rolling elements (wear)
- Combined loading
- Outer/inner race curvature factors
- Variation in cage pocket shape

A sensitivity analysis of bearing behavior is illustrated in Figures 2-17 through 2-20. The study of bearing dynamics represents a continuing effort to define with greater accuracy ball bearing signatures for prediction of wear and/or incipient bearing failure. Application of the techniques, summarized in this section, are discussed more fully in the Appendices to this report.

2.5.4 Statistical Characterization of SSME Data

A comprehensive statistical data base of vibration spectra, representing SSME-component response over a wide range of engine operating conditions, has been developed. These data are invaluable in the efficient assessment of hot firing test results. Measurements from over 2000 hot firing tests, with an average of 19 vibration measurements per test, are presently stored. Table 2-1, at the end of this report, is a log of all SSME hot firings, including flights. Extensive statistical analyses have been applied utilizing this data base, primarily to

- Classify (statistically) measurements by location, engine operating conditions, and component condition.
- Discriminate between nominal and abnormal component operation.
- Establish vibration redlines and flight certification acceptance criteria.

Figures 2-21 and 2-22 illustrate the statistical variation in shaft speed for the ATD turbopump, during nominally constant power level operation. Such results are useful in the interpretation of component response measurements since rotational component frequencies (turbine blades, bearing elements, etc.) of interest will vary with shaft speed.

Operating redlines (vibration, pressure, temperature, etc.) are utilized to terminate, or otherwise alert, SSME test operations in order to minimize the possibility of damage to equipment or personnel. Turbopump vibration measurements provide a significant input to test operation decisions. Detailed statistical analyses are required to establish these criteria. During Space Shuttle flight, a Flight Accelerometer Safety Cut-off System (FASCOS) is utilized to monitor SSME turbopump vibrations. (This system is not yet active in the loop.) Similar analyses are required to assess flight certification (green run) acceptance levels. Vibration acceptance criteria for the operational SSME turbopumps are summarized as follows:

- **HPFTP Acceptance Criteria @ 104%-109% RPL**
 Synchronous (1N) - pump end/turbine end grms: 7.5 max/7.5 max
 3X synchronous (3N) - pump end/turbine end grms: 7.5 max/11.0 max
 Any subsynchronous on HPFTP shall be addressed during acceptance review

 LPFTP Acceptance Criteria @ 105% - 109% RPL
 Synchronous (1N) - pump end/turbine end grms: 3.0 max/4.5 max
- **HPOTP Acceptance Criteria @ 104% - 109% RPL**
 Synchronous (1N) - pump end/turbine end grms: 3.0 max/3.0 max
 Cage Frequency Harmonic Amplitude: any sustained (two or three consecutive data samples) amplitude strain placed on the ball cage frequency harmonics is not acceptable
 Any subsynchronous on HPOTP shall be addressed during acceptance review

 LPOTP Acceptance Criteria @ 104%/109% RPL
 Synchronous (1N) - pump end/turbine end grms: 1.0 max/1.0 max

The sample mean and standard deviation of a collection of measurements provide a simple and useful measure of the 'center of gravity' and dispersion of the data. In addition, such statistics can be used to estimate the probability distribution for representing the data set. Classical distributions provide a useful tool for modeling empirical measurements. This permits direct comparison of newly observed results, with previous trends. Fundamental steps in the assignment of analytical distributions to represent a collection of data, include the selection of reasonable analytical models, and performance of tests to gauge how well a selected model fits the empirical data set. Figures 2-23 and 2-24 illustrate the 'fit' of three theoretical distributions to the empirical distribution of recent ATD turbopump vibration measurements. The mean-square error noted on the figures indicates the relative goodness-of-fit between each theoretical distribution and the observed measurements. Application of statistical techniques to SSME evaluations are discussed further in Appendix A. Specific tasks performed under the subject contract are summarized in the next section.

2.6 Task Requirements and Accomplishments

The basic objectives of this study were to perform detailed analysis and evaluation of dynamic data obtained during SSME test and flight operations, including analytical/statistical assessment of component dynamic performance, and to continue the development and implementation of analytical/statistical models to effectively define nominal component dynamic characteristics, detect anomalous behavior, and assess machinery operational condition. Our overall goal was to provide timely assessment of engine component operational status, identify probable causes of malfunction, and define feasible engineering solutions. The work performed under this contract may be summarized by the three broad task areas outlined below. Consistent with stringent SSME test and flight certification schedules, test evaluation and the resolution of discrepancies were given priority throughout the study.

Data Analysis, Evaluation and Documentation. This task represented the major contract effort and included data verification, analysis, and documentation for each SSME ground test and, additionally, for all SSME flight measurements. Advanced component tests performed at NASA and contractor facilities were also supported. This included ATD and TTB data analysis, as required. Results included definition of temporal and spectral characteristics observed. Spectral values associated with rotor/shaft dynamics, bearing elements, and the like were identified and summarized for engine components under all operating conditions, permitting comparison with previous test and flight results. Extensive utilization of the SSME automated data base system was made to provide timely, informative data summaries. Informal oral and/or written summaries to support

FIGURE 2-23. ATD CUMULATIVE HISTOGRAM COMPOSITE @ 100 % PWL

FIGURE 2-24. ATD DENSITY HISTOGRAM COMPOSITE @ 100% PWL

assessment of each test and to document the results was provided, including recommendations as to the integrity of the engine system and components.

Discrepancy investigations were conducted on tests or flights exhibiting abnormal system operation or anomalous dynamic behavior. This effort made use of the automated data base and Operator Interactive Signal Processing System (OISPS) analytical capabilities and included time/event correlations and spectral and temporal trend comparisons with previous component heritage and available models and correlations with operational performance data. These results were applied to identify probable causes of malfunction and approaches to their resolution. Failure analyses required routine application of the advanced software operational on the OISPS, including hypercoherence, phase-domain averaging, and nonstationary (modified Wigner) spectral methods. Close coordination of these efforts with MSFC was maintained.

Data Base Development and Applications. Wyle engineers utilized the automated data base and associated statistical models of SSME component dynamic response to generate characterizing profiles of observed parametric ranges, distributions, etc., under nominal and abnormal engine operating conditions at all power levels. These statistics were applied directly to support the above data analysis effort. Parametric and nonparametric tests were applied to test for homogeneity between measurement location and operating condition. Similar analyses were performed to refine and update Redline Accelerometer Safety Cut-off System (RASCOS) and turbopump flight certification ("green-run") vibration levels, most recently for the ATD turbopump design. Algorithms were implemented to increase the efficiency of quick-look data assessment/component evaluation.

Application and Refinement of Vibration Diagnostic Techniques. Under this task, Wyle continued the development, update, and application of signature analysis techniques for detailed SSME and advanced system diagnostic evaluation. A number of advanced time domain and spectral evaluation algorithms were developed and implemented on the OISPS. These algorithms include nonstationary spectral techniques, nonlinear coherence methods, and advanced adaptive filtering techniques. Application of these methods was provided for efficient and immediate assessment of machinery condition. In addition, analytical models were developed and applied to provide improved identification of bearing element wear, whirl onset, squeal, rubbing, and other types of component degradation. Analyses were conducted to identify component failure signatures and

other anomalous indications that can be used to indicate component health. All software developed under this contract was implemented on the OISPS, resident at MSFC. A series of tutorial seminars was conducted to describe application of the advanced algorithms implemented on MSFC computers.

A log of SSME hot firings, including flights, is included in Table 2-1. Over the course of this study, data analysis support was provided for 456 SSME hot firings, including 372 single engine tests and 28 STS flights. Of the single engine tests, 38 included instrumented ATD turbopump configurations. Additional data analysis was provided for component tests at the MSFC Technology Test Bed, water flow facility and various contractor locations. As a test/evaluation program, rigid, long term task planning was neither feasible nor desirable. On the contrary, most tasks performed under this contract were initiated on an ad hoc basis, motivated by observed or suspected SSME component failure modes. Continued coordination with the MSFC COTR was, therefore, mandatory to revise task priorities based on SSME test results and Project Office requirements. To support SSME test and flight requirements, evaluation results were immediately provided the COTR in the form of presentations and informal data packages. To illustrate the diversity of tasks accomplished under this contract, some reports and presentations prepared by Wyle in support of SSME dynamic evaluations are summarized below. *It should be emphasized that most of these reports represent a collaborative engineering effort* between Wyle and MSFC personnel.

Selected reports, or their abstracts, from the above list are included in Appendix A. These reports provide detailed discussion of specific data analysis and modeling efforts performed and the signal processing techniques developed and applied to SSME diagnostic evaluations. The Technical Progress Reports, generated in the course of this study, give a monthly chronology of investigations performed, techniques applied and interim results obtained. Appendix B includes the course notes for a MSFC seminar series on Advanced Signal Processing Techniques, prepared by Dr. J. Jong of Wyle, under this contract. In addition to documenting the efforts of this study, these two appendices provide a comprehensive overview of the SSME data analysis and diagnostic evaluation process, and computational methods, which should prove useful as an orientation guide for analysts new to the field.

The TOPO Plot: A Data Reduction/Graphics Routine for Tracking Spectral Trends in Vibration Data

(T. Coffin & J. Y. Jong)

In support of space shuttle main engine (SSME) development and advanced technology test programs, a number of sophisticated diagnostic algorithms have been integrated into the Operator Interactive Signal Processing Systems (OISPS) operational on MSFC's Structures and Dynamics Laboratory computers. These include nonlinear spectrum analysis, adaptive filtering, envelope detection, and other analytical methods applicable to specific SSME mechanical symptom detection and identification investigations. For quick-look data assessment, the (linear) power spectral density (PSD), isoplot, and root-mean-square (rms) time history of a measurement are the most basic and valuable computational tools. When viewed in the context of empirical statistical data representing SSME component measurements obtained under similar operating conditions, these analyses can provide a quick, qualitative indication of component "health" (from a dynamics standpoint) and signal any gross deviations from nominal operation.

The most fundamental "signature" used to characterize an SSME vibration (acceleration, pressure, strain, etc.) measurement is the mean-square density spectrum, or power spectral density. Figure 23a illustrates an isoplot, or family of spectra, from a strain gauge measurement representing 450 seconds during a hot-firing test. The PSD provides a detailed snapshot of conditions over an interval of (usually) constant power operation. In contrast, the isoplot yields a more qualitative indication of amplitude/frequency trends over a complete hot-firing test or powered flight. These plots are particularly useful for detecting the *time* of any significant deviations in the vibration signature and correlation with engine operating parameters (power profile, programmed venting, etc.). Figure 23b shows an alternate format.

Figure 23. Illustration Isoplot Format

Figure 24. TOPO Plot of Bearing Displacement During Speed Change

The PSD isoplot has been used extensively to display spectral components in a frequency/time/amplitude format. This display is especially useful for nonstationary data, which allows one to trace any particular frequency component as a function of time. However, there are several limitations to the procedure.

- For clarity, a threshold level has to be chosen when plotting an isoplot in which some possibly significant peaks with PSD amplitude lower than the threshold are excluded.
- For a nonstationary case, when manned PSD peaks are crowded together, or crossover occurs, it is difficult to identify the trace of some peaks. Then, it is necessary to subdivide the entire frequency range into several smaller ranges and plot the results separately.
- The number of PSD's which can be legibly displayed in an isoplot is limited to approximately one hundred.

To provide improved tracking of spectral trends, a new method called "TOPO" (for Topographic Plot) was developed and programmed. The method uses a novel peak-identifying routine to pick out all

meaningful peaks in each PSD and assign a "peakyness" parameter for each identified peak. Each peak is then plotted on a TOPO plot as a dot whose width is proportional to the "peakyness" parameter associated with the peak. Figure 24 is an example of bearing test data during ramp-up. Four hundred PSD's are plotted in this figure, and the non-stationary and crossover can be clearly visualized.

The TOPO plot technique has been integrated in the OISPS program and is in routine use for SSME data evaluations. For computerized data base application, the technique provides significant data compression since only spectral peak values need be stored. Enhancements in the graphic output format, to aid in data interpretation, are presently under evaluation, including color coding of amplitude ranges.

An Algorithm for Periodic Waveform Recovery from Space Shuttle Main Engine Vibration Measurements

(T. Coffin & J. Y. Jong)

The frequency content in dynamic measurements from rotating machinery contains much subtle information concerning equipment operating condition and component degradation. For this reason, the power spectral density (PSD) has long been employed to assess the relative magnitude of fault-related spectral contributions. Measurements on high-performance rocket engine turbomachinery suffer from severe noise contamination, from numerous extraneous sources, which impedes rotating element diagnostic evaluation. Thus, it is difficult to determine whether an apparent high-level harmonic contribution is indeed related to the fundamental rotational frequency, f_r , or possibly due to an independent source. In an effort to correlate synchronous frequency characteristics with an arbitrary harmonic component, a unique coherence spectrum was devised which we call the "hypercoherence" function. The hypercoherence function, $\Gamma(n;f)$, defines the nonlinear correlation between waves at a reference frequency, f , and harmonics at nf , $n = 1, 2, \dots$

Application of the hypercoherence functions to SSME turbomachinery diagnostic data assessment was summarized in the 1986 R&T Report (NASA TM 86567). This frequency-domain analysis has since been extended to a time-domain filtering algorithm for the extraction of periodic signals in noisy data. Assume we have two turbopump vibration measurements located (approximately) 90° apart radially about the casing, say $X(t)$ and $Y(t)$. If the shaft (and inner bearing race) motion is sensed by these transducers, a plot of $X(t)$ versus $Y(t)$ should indicate the orbital motion of the shaft end measured. Each of these "signals" will clearly be corrupted with undesired noise (both random and periodic) during practice. The analytical basis for the techniques can be summarized briefly. Assume $X(t)$ and $Y(t)$ jointly periodic, with additive uncorrelated noise and (possibly coincident) period components.

Let

$$X'(t) = F^{-1} [\sqrt{S_x(nf)} \Gamma_x(nf, f)]$$

$$Y'(t) = F^{-1} [\sqrt{S_y(nf)} \Gamma_y(nf, f)]$$

where

$$n = 1, 2, 3, \dots$$

S = Ordinary power spectrum

G = Hypercoherence function

F^{-1} = Inverse Fourier transform

Now X' and Y' represent filtered time histories, and include only harmonics (nonlinearly) correlated with the common fundamental frequency. To generate an orbit plot, or phase-plane representation of the two quantities, let

$$Y''(t) = Y'(t - \tau)$$

$$\tau = \phi / 2\pi f_1$$

$$\Phi = \tan^{-1} [Q_x(f_1) / C_x(f_1)]$$

Q_x = QUADRATURE SPECTRUM

C_x = COSPECTRUM

The time delay, τ , serves as a "key phasor," to initiate the relative phase angle between the two vectors. A phase-plane diagram of the filtered signals is thus obtained by plotting X' versus Y'' . The procedure is best illustrated by example. Figure 122a illustrates the orbit plot for two jointly periodic signals, each containing three harmonic components. Figure 122b represents the same plot when uncorrelated noise and independent, coincident pe-

riodic components have been added to each signal. This chaotic pattern is highly representative of hot firing data. Figures 122c and 122d are the recovered orbital diagrams by hypercoherence filtering and comb filtering, respectively. The superior performance of hypercoherence filtering is clearly indicated.

When compared with available noise cancellation methods, such as time domain averaging (TDA), comb filtering, and adaptive line enhancement, the hypercoherence filter has the following two

advantages: (1) only the hypercoherence filter can reject independent components at the same frequency (while the other noise cancellation methods will pass all data in the pass-band including both true harmonics and independent components); (2) a slight phase drift would be fatal for techniques, such as the TDA method, which require precise phase lock-in. For the hypercoherence filter, on the other hand, since only relative phase information is required, slight phase drifting is not as critical. This is significant when considering the small speed variations inherent in turbopump operation, even at a constant power level.

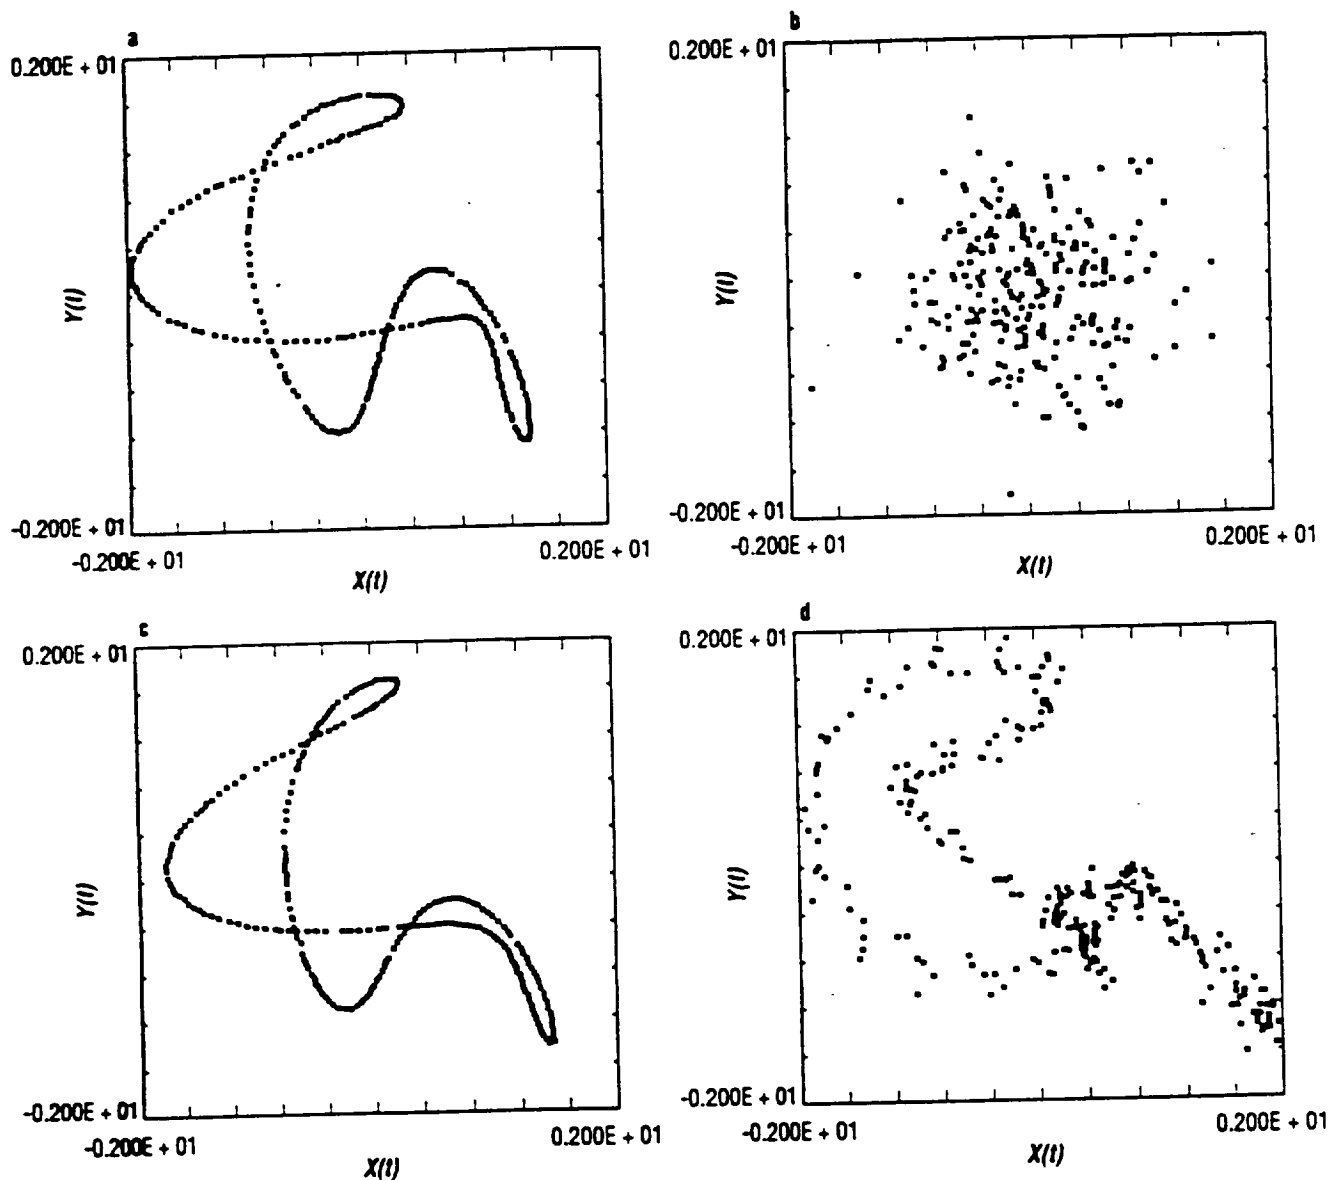

Figure 122. (a) Orbital Diagram of Noise-Free Simulation, (b). Orbital Diagram of Simulation With Additive Gaussian White Noise, (c). Recovered Orbital Diagram by Using Hypercoherence Filtering, (d). Recovered Orbital Diagram by Using Comb Filtering

Figures 123a and 123b represent the filtered orbits from measurements at HPFP rad-90° and rad-170° during SSME tests 901-471 and 901-436, respectively. Figure 123a has a smooth orbital motion which represents a well behaved rotational system. Figure 123b, however, indicates a potential rubbing problem. The two locations with sharp cusps appear to indicate possible impact between stationary and rotating system components.

Figure 123. Orbital Plot From Test 901-471 by Hypercoherence Filtering, b. Orbital Diagram of 901-436 by Hypercoherence Filtering

The above algorithm is presently operational and has been integrated into the SSME Diagnostic Analysis Package developed by Structures and Dynamics Laboratory.

CORRELATION IDENTIFICATION BETWEEN SPECTRAL COMPONENTS IN TURBOMACHINERY MEASUREMENTS BY GENERALIZED HYPERCOHERENCE

Jen Y. Jong, Thomas Coffin

Wyle Laboratories
Huntsville, Alabama

Jess H. Jones, James E. McBride, Preston C. Jones

National Aeronautics and Space Administration

ABSTRACT

In a rotordynamic system, the fundamental shaft rotation can be considered a source which drives other mechanisms and generates new spectral components associated with, say, gear tooth meshing or bearing element passage. The frequency content in measurements from such machinery contains much subtle information concerning system operational condition and component degradation. Measurements on high performance rocket engine turbomachinery suffer from severe noise contamination from fluid flow, combustion processes, structural resonances, etc. It is thus impossible, based on linear spectrum analysis, to determine whether a high level spectral contribution represents a rotational component frequency or an independent noise source. To detect such components, higher order spectrum analysis is required. However, the hierarchy of cumulant spectra (bispectrum, trispectrum, etc.) exist only for frequency permutations where the sum of the arguments vanishes. This does not permit direct estimation of the correlation between arbitrary frequency component pairs. The hyper-coherence function^(1,2,3) was developed to detect the correlation between synchronous frequency characteristics and any *harmonic component*. The generalized hypercoherence, described in this paper, permits estimation of the nonlinear correlation between any selected reference frequency (e.g., shaft speed) and an *arbitrary* suspect frequency component. The approach is based on estimating the temporal correlation between the rate of change of instantaneous component phases. Application of the technique to extract component signature characteristics is illustrated with vibration measurements from the space shuttle main engine.

NOMENCLATURE

PSD	Power spectral density function
HC	Hypercoherence
GHC	Generalized hypercoherence
PLL	Phase lock loop
N	Synchronous (shaft rotating) frequency
C	Cage frequency
OBP	Outer ball pass frequency
SYNC	Synchronous frequency component
FM	Frequency modulation
M	Gear tooth number
R	Gear ratio
$f_i(t)$	Instantaneous frequency time signal
$p(t)$	Instantaneous phase
IF	Instantaneous frequency
SSME	Space shuttle main engine
HPOP	High pressure oxidizer pump

LINEAR AND HIGHER ORDER SPECTRA

Conventional linear spectral analysis⁽⁴⁾ has long been used to identify the signal characteristics associated with machinery faults in vibration signature analysis. However, nonlinearities can play a significant role for signature identification. It has been observed that different rotational mechanisms may interact due to some nonlinear process^(5,6,7). When this occurs, coherent phase relationships may exist, which can be identified from response signals. Frequency sum and difference components are one of the commonly observed nonlinear (quadratic) phenomena. A typical example is a synchronous (shaft rotational) frequency component modulated by subsynchronous whirl⁽²⁾. Other kinds of nonlinearity include high level harmonic content of synchronous vibration due to waveform clipping from rubbing⁽³⁾. All these signals represent nonlinear phenomena since their spectral components at different frequencies are not independent of each other. Due to the lack of phase information, traditional PSD analysis cannot identify such phenomena. Therefore, higher order spectral analysis is required. This analysis includes a hierarchy of cumulant spectra such as auto/cross-bicoherence, tricoherence, etc. Each technique can identify nonlinearities of different order in a random signal and be applied to the particular type of failure mechanism to be detected.

Bispectral analysis can be used to identify the existence of amplitude modulation (quadratic correlation) among spectral components. Enrich and Eshleman⁽⁶⁾ have described six analytical models to explain how these modulations may be physically generated. The bispectrum measures the degree of correlation by identifying phase relationship among three spectral components f_1 , f_2 , f_1+f_2 , i.e., frequency sum or difference. It has been applied to identify the quadratic phenomenon of a synchronous frequency component modulated by the cage frequency in a ball bearing and a synchronous component modulated by a 50-percent subsynchronous whirl frequency component⁽²⁾.

Trispectrum can be used to identify cubic correlation among four spectral components. A special case of its application is to determine whether an apparent PSD sideband structure is really due to modulation or not. Such a sideband structure is another commonly observed nonlinear defect signature. A typical example of this is a bearing cage frequency component periodically exciting a structure natural frequency. In this case, the envelope signal represents the periodic impact motion, and the carrier represents the structural response at a dominant natural frequency. Notice that such a sideband does not satisfy

the frequency sum or difference requirement; therefore, the bispectral analysis is not applicable. Envelope detection by using a Hilbert transform can recover the envelope signal and its PSD since the carrier frequency is shifted to zero frequency in the Hilbert transformation. But it cannot indicate whether this sideband structure is correlated or not.

The harmonic components of a vibration signal contain subtle information about machine condition. Many failure modes, such as misalignment, loose coupling, and rubbing, will generate harmonics. For example, rubbing may cause waveform clipping and generate strong odd harmonics. However, many independent sources may generate a spectral component at the same frequency and appear to be a harmonic. In this case, the hypercoherence^(1,3) can identify whether an apparent spectral peak is a harmonic or independent noise. The hyperspectrum represents the joint moment between a spectral component and its harmonics. Hypercoherence (HC), which is the normalized hyperspectrum, can identify the degree of correlation between a reference component and its harmonics.

As discussed above, the spectral components to be identified by higher order spectra are required to satisfy certain frequency combinations (e.g., the sum of arguments is zero). However, in many situations, we wish to identify the correlation between two arbitrary frequency components that do not satisfy any such requirements. The generalized hypercoherence (GHC) was developed to deal with this situation. The GHC can identify the correlation between two arbitrary spectral components in the sense of frequency synchronization or lock-in.

THE GENERALIZED HYPERCOHERENCE

Consider a gear box with gear ratio R as shown in figure 1. The angular displacements (phases) at frequencies N_1 and N_2 will be proportional to each other, and these two spectral components are correlated in that their phase variations are synchronous. This can be seen by marking a key phasor in each of these two gears to monitor their angular displacement. If key-phasor A goes through one cycle of rotation with angular displacement $a(t)$, then key phasor B will finish R cycle of rotation with angular displacement $R \cdot a(t)$. Their angular displacements will be proportional to each other by factor R . As a result, coherent phase will exist between the spectral components at frequencies N_1 and N_2 . In general, however, the gear ratio R may be an irrational number. Such phase

Fig. 1. Gear Box with Gear Ratio $R = N_1/N_2$. The rotational frequency components are correlated to each other.

coherence is difficult to identify. To see this, consider the case when the gear ratio is an integer K . In this case, the HC can identify their phase correlation. This is because the ambiguity introduced by the Riemann surface phase wrapping is within an integer multiple of 2π , which does not affect the coherence estimation. However, if the ratio is not an integer, phase wrapping will introduce a noninteger multiple of 2π , which yields ambiguous phase. Therefore, phase correlation cannot be uniquely identified in the phase domain. Based on this observation, the GHC was developed to identify such phase coherence by correlating the rate of change of phase, which is also called the instantaneous frequency. By taking the time rate of change of phase, the ambiguous term is eliminated, and the phase correlation is reflected in the frequency domain as frequency synchronization.

A vibration signal may be treated as an FM signal with different spectral components at different center (carrier) frequencies. Assume that there is some intelligence being frequency modulated in the signal as the instantaneous frequency about these carriers. To recover the intelligence, we demodulate the FM signal to estimate its instantaneous frequency signal. A narrow-band random process can be modeled as a sine wave with slowly varying amplitude $A(t)$ and phase $p(t)$:

$$x(t) = A(t) \cos [2\pi f_c t + p(t)] \quad (1)$$

The instantaneous frequency $f_i(t)$ is defined by:

$$f_i(t) = \frac{d p(t)}{d t} \quad (2)$$

Figure 2 shows the block diagram of a FM demodulator by using the Hilbert transform method. The input signal may contain several spectral components (FM signals) at different carrier frequencies. Here, the 90-degree phase shifting is performed through multiplication by locally generated sinusoid and cosine waves (synchronous receiver) at the desired carrier frequency. This will effectively shift the spectral component from the carrier frequency to both zero and two times that frequency. A low-pass filter is then used to remove any high frequency component. The output of the low-pass filters then represent the slowly varying amplitude and phase components that have been frequency translated. The instantaneous frequency signal then can be obtained by:

$$\dot{p}(t) = [u(t) \dot{v}(t) - \dot{u}(t) v(t)] / [u^2(t) + v^2(t)] \quad (3)$$

These outputs can be represented as

$$\begin{aligned} u(t) &= A(t) \cos [p(t)] \\ v(t) &= A(t) \sin [p(t)] \end{aligned}$$

Fig. 2. Hilbert Transform Demodulation Using Synchronous Receiver

Figure 3(a) shows another FM demodulator by using the phase lock loop (PLL)⁽⁸⁾ technique. The desired carrier frequency for FM demodulation is determined by the frequency in the Voltage Control Oscillator (VCO) in the feedback loop. The output $y(t)$ of the PLL will be an estimation of the instantaneous frequency. To see this, the PLL can be shown as a nonlinear model in figure 3(b). It can be shown that the phase error signal $e(t)$ tends to drive the PLL into lock. That is, any phase deviation will converge to some steady state operating point. When the PLL is operating in lock, the VCO phase, $q(t)$, is a good estimate of the input phase, $p(t)$. Therefore, the sinusoidal nonlinearity in figure 3(b) can be neglected, since $p(t) - q(t)$ is small, and

$$\sin [p(t) - q(t)] = p(t) - q(t) \quad (4)$$

Therefore, the PLL becomes a typical linear feedback system with transfer function:

$$H(f) = \frac{Y(f)}{P(f)} = \frac{j2\pi f}{1 + j2\pi f/K} \quad (5)$$

The loop constant K will control the frequency deviation range (lock range) for the PLL to lock. If K is large, the term $j2\pi f/K$ in equation (5) can be neglected, and the transfer function becomes

$$H(f) = j2\pi f \quad (6)$$

which is the transfer function of a differentiator, d/dt . Therefore, the output signal will be a good estimate of instantaneous frequency.

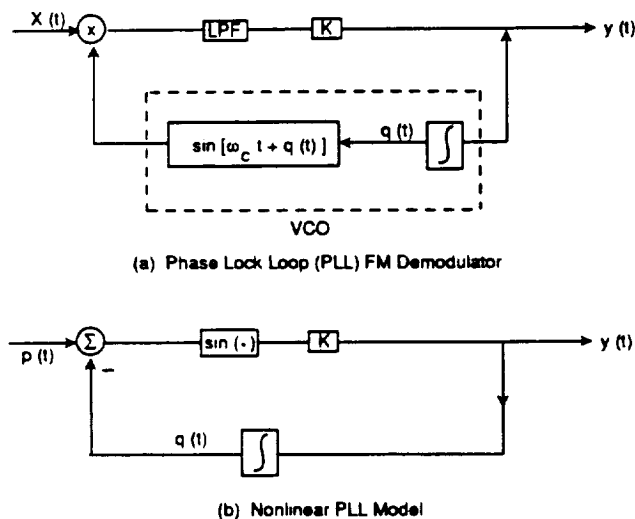

Fig. 3. Schematic of an FM Demodulator

For the purpose of identifying frequency synchronization for machinery diagnostics, imagine that the vibration signal is composed of several FM signals modulated at different carrier frequencies as shown in figure 4. Each component is then passed through an FM demodulator to generate a series of new random signals. Each one represents the instantaneous frequency signal at each carrier frequency. A linear correlator is then used to correlate these signals with a specified reference carrier frequency. Their correlations are then summarized in the frequency domain to generate the GHC.

Fig. 4. GHC Through FM Demodulator

A SIMULATION MODEL

A simple simulation is used to demonstrate the GHC. Consider a gear train with 16 and 9 teeth respectively. The first gear is rotating at frequency f , with phase $p(t)$. The angular displacement of these two gears will be proportional by a factor of 1.78. The simulation signal is composed of three spectral components. The first corresponds to the synchronous frequency component of the first gear, i.e., reference frequency. The second one is the SYNC of the second gear at center frequency $1.78 f$, with proportional phase 1.78 times $p(t)$. The third represents a component at frequency 1.36 times f with independent phase $q(t)$. Therefore, the third component is uncorrelated with the other two. The reference frequency is at 500 Hz with a sampling rate of $10,240$ Hz. A total of 20 seconds of data was generated. Figure 5(a) shows the PSD of the simulation signal with 50 averages of 4096 -point FFT blocks. It is composed of three spectral components marked by R, U, and C, which represent the Reference, Uncorrelated, and Correlated component, respectively. Figures 5(c), (d), and (e) show the demodulated instantaneous frequency signal with carrier frequencies set at R, U, and C respectively. Strong correlation or synchronization can be clearly seen between the reference and correlated component while no correlation is indicated with the independent component. The linear correlation between these frequency variations is summarized in figure 5(b).

Also, notice that during this 20 -second time period the instantaneous frequency variations are much smaller than the

Fig. 5. Illustration of the GHC Method

bandwidth of the PSD estimator which is 2.5 Hz. As shown in figure 5(c), the frequency variation for the reference component is only about 0.015 Hz, which is less than one percent of its PSD frequency resolution. Therefore, frequency tracking from a typical PSD isoplot or its Wigner time-frequency distribution⁽⁹⁾ would not provide adequate frequency resolution to identify this synchronization.

APPLICATION TO MACHINE DIAGNOSIS

Synchronous/bearing signature correlation. Figure 6(a) shows the PSD of a strain gauge measurement taken from a SSME High Pressure Oxidizer Pump (HPOP) hot firing test. The peak marked 5.7N is located at 5.7 times shaft frequency N, near the predicted outer ball pass (OBP) frequency and a possible defect indication. However, many independent sources, such as a feedthrough from nearby pump units, confound signature identification. To determine whether this is indeed an outer race defect signature, the GHC analysis was performed to discover whether this 5.7N OBP component is synchronized with the SYNC component. Figures 6(b), (c), and (d) show the instantaneous frequency variation of components N, 5.7N, and an arbitrarily chosen component at

500 Hz. Strong frequency synchronization is identified between components N and 5.7N and no correlation between components N and noise at 500 Hz. This indicates that the 5.7N is a sync-related component and a potential outer race defect signature.

Figure 6. Correlation Detection by GHC

Identification of composite modulation. The GHC technique can also be applied to identify a more complicated modulation signal, the so-called "composite-modulation" phenomenon. As noted above, the bispectrum is useful for identifying the correlation between a "carrier" frequency and a modulating component signal. However, it has been observed that modulation may exist between a harmonic of the shaft speed and a harmonic of a subsystem frequency without these harmonics showing up in the linear PSD. In such cases, direct (nonlinear) spectrum analysis is impractical. This composite-modulation phenomenon was observed in SSME vibration measurements associated with a bearing element defect as shown in figure 7. This PSD is taken from the SSME HPOP internal bearing strain gauge measurement during a hot firing test. The peaks marked N, 2N, 4N, etc., are the synchronous frequency component and its harmonics. The other peaks marked C and 2C are the bearing cage frequency components and are considered normal in such internal measurements. However, a

strong anomalous component marked A is observed around frequency $8.5N$. To assess this anomaly, we need to determine whether it is correlated with the cage or the sync frequency component.

Fig. 7. Strain Gauge Measurement Showing Anomalous Component A at $8.5N$

By examining the frequencies of these components, it is observed that the $8.5N$ is equal to $14N - 12C$, or $12(N - C) + 2N$. This implies that the $8.5N$ component might be caused by the modulation between the inner ball pass component (for a 12-ball bearing set), which is at frequency $12(N - C)$, and the second harmonic of SYNC at $2N$. In other words, this could be a composite-modulation. If the existence of such modulation can be proven, then the anomalous $8.5N$ component would represent a bearing-related signature. However, the spectral components at $14N$, $12C$, and $12(N - C)$ are not shown in the PSD. Therefore, the bispectrum or trispectrum cannot identify such composite-modulation. Notice that, for this particular case, the ninth order cumulant spectrum at frequencies

$$2N, 4N, 8N, -2C, -2C, -2C, -2C, -2C, -2C$$

should be able to identify this modulation since the PSD shows spectral components at frequencies $2N$, $4N$, $8N$, and $2C$. However, whenever multiple phase components are summed, the effect of noise will accumulate while that of signal will not because of the Riemann surface phase wrapping. As a result, such noise expansion effect at this high order will smear the coherent phase information and make it difficult to identify any significant coherence value.

Such noise growth in the phase domain will not exist in the instantaneous frequency domain. Thus, we can identify the composite modulation by simply matching the appropriate integer multiple of each instantaneous frequency signal corresponding to each modulating component. In this example, the carrier frequency of the FM demodulator is tuned to the cage frequency C , the SYNC frequency N , and the anomalous frequency A to generate their IF signal as shown in figures 8(a), (b), and (d). Figure 8(c) shows the summation of 12 times the IF signal of C and 14 times the IF signal of N . Theoretically, this composite IF signal should be equal to the IF signal at frequency $14N - 12C$ due to modulation of $14N$ and $12C$. Compare this to figure 8(d), which is IF of the anomalous

component A. Strong correlation can be identified between them. Figure 9 shows the same information over a longer time period. Therefore anomaly A turns out to be SYNC- and cage-related component likely being generated from the modulation of the inner ball pass frequency at $12(N - C)$ and 2 times SYNC at $2N$.

Fig. 8. Detection of Composite Modulation

Fig. 9. Same as Fig. 8 Except for Over Long Time Period

The IF signal reflects the micromotion of a vibration spectral component. Therefore, any independent interference will disrupt such micro-information. Thus, any bearing contact angle variation or ball slippage will disrupt such frequency correlation. This can be seen in figures 8(a) and (b) where no significant correlation can be identified between the IF signal of SYNC and cage components.

CONCLUSIONS

By estimating the instantaneous frequency (IF) signal of a narrow-band spectral component, the GHC can be used to

identify the nonlinear correlation among arbitrarily chosen frequency components. This method is especially useful for machinery diagnostics, in which case a driving source generates many frequency components that may be severely contaminated with noise. In addition, the IF signal reflects the microfrequency variation for a seemingly stationary spectral component. It can identify frequency variations much smaller than the frequency resolution of a conventional PSD estimator or even that of a maximum entropy PSD estimator or obtained using the Wigner distribution. The GHC method should provide a useful addition to the tools available for the difficult task of machinery fault detection and identification.

TIME-FREQUENCY REPRESENTATION OF NONSTATIONARY SIGNALS VIA THE MODIFIED WIGNER DISTRIBUTION

Jen Y. Yong, Thomas Coffin
Wyle Laboratories, Huntsville, AL

Thomas F. Zoladz, Jess H. Jones

ABSTRACT

This report presents a new signal analysis technique called the Modified Wigner Distribution (MWD). The MWD has been developed for the Structures and Dynamics Laboratory at MSFC by Dr. Jen-Yi Jong of Wyle Laboratories. The new signal processing tool has proven very successful in resolving time-frequency representations of highly nonstationary multicomponent signals in both simulation and trials involving Space Shuttle Main Engine (SSME) high frequency data. The MWD departs from the classic Wigner Distribution (WD) in that it effectively eliminates the cross coupling among positive frequency components in a multiple component signal. This attribute of the MWD, which prevents the generation of "phantom" spectral peaks, will undoubtedly increase the utility of the Wigner Distribution for real world signal analysis applications which more often than not involve multicomponent signals.

TECHNICAL PAPER

TIME-FREQUENCY REPRESENTATION OF A HIGHLY NONSTATIONARY SIGNAL VIA THE MODIFIED WIGNER DISTRIBUTION

I. INTRODUCTION

This report describes and evaluates a new signal processing technique called the modified Wigner distribution (MWD) used for the spectral analysis of highly nonstationary multicomponent signals. The regular Wigner distribution (WD) is capable of providing high resolution time-frequency estimates of nonstationary signals which are common in many fields including the dynamic response of rotating machinery. A traditional tool for such analysis has been the short-time Fourier transform (STFT), commonly referred to as "overlap" processing, which is obtained by applying a fixed-length moving time window to nonstationary data prior to performing the fast Fourier transform (FFT). However, if spectral components within the signal vary considerably in frequency during the time window, the STFT often fails in providing enough frequency resolution to identify key time-frequency spectral characteristics.

The WD was originally introduced in 1932 by E. Wigner.¹ It received little attention until 1980 when Claasen and Mecklenbrauker² presented a comprehensive three-part paper describing the utility of the WD as a tool for time-frequency analysis of nonstationary signals.

Major obstacles arise in the direct use of the WD. Most notable of these problems are aliasing and the generation of artifacts or "phantom" spectral peaks in the resultant time-frequency distribution. A number of attempts, with varying degrees of success, have been employed to minimize these effects.³⁻⁵ This paper presents yet another approach. With the introduction of the "smart window," this approach will hopefully overcome these obstacles.

The MWD will have important application in turbomachinery diagnostic analysis. It is particularly suited to those turbomachinery operations which are highly transient, i.e. during startup or ramping conditions. It can also be an important diagnostic tool in failure analysis where the dynamic signals are highly nonstationary.

II. THE WIGNER DISTRIBUTION

The WD is a powerful tool in determining the time-frequency characteristics of a highly nonstationary signal. The technique has been applied successfully in the identification of abnormal machine operating states through vibration signal analysis.³ Other applications of the WD include the analysis of time-varying spectra in optics, speech, sonar, and seismic signal processing.

The WD of a real signal $r(t)$ is given by:

$$W(t, f) = \int z(t + \tau/2) z^*(t - \tau/2) e^{j2\pi f \tau} d\tau, \quad (1)$$

where $z(t)$ is the analytic signal of $r(t)$, $z(t) = r(t) + j i(t)$, and $i(t)$ is the Hilbert transform (HT) of $r(t)$, $i(t) = \text{HT}\{r(t)\}$. Let the absence of limits on the integral symbol denote the interval $(-\infty, \infty)$. In equation (1), $z^*(t)$ represents the complex conjugate of the analytic signal $z(t)$. Therefore, the WD is the Fourier transform (FT) of the product between the original forward signal and corresponding backward signal both centered at time t . If the frequency of a subject narrowband signal is either monotonically increasing or decreasing within its time window, the product of this forward and backward signal will provide frequency cancellation, and, as a result, will estimate a frequency corresponding to the signal frequency at the center of the time window. However, the product in equation (1), which serves as the kernel of the FT, introduces a frequency summing effect. Taking a real single component signal with a discrete component at f_o as an example, the summing effect produces a peak in the WD spectrum at $2f_o$. For this reason, equation (1) scales the subject time signal by two. However, this scaling is only aesthetic and does not relax sampling constraints on the time signal. If $2f_o$ is greater than the original Nyquist frequency (determined when the subject time signal was originally sampled) aliasing within the WD spectrum will occur. For this reason, an analytic signal is used in equation (1) since it has no energy at negative frequencies. Aliasing due to the frequency summing effect can now be avoided, and, in addition, frequency difference effects (coupling between positive and negative frequency components) are eliminated. Essentially, use of the analytic signal in equation (1) returns the sampling rate constraint for a subject time signal back to its original Nyquist rate.

Prior to introducing the MWD, sample graphical illustrations of the WD for cases involving simple sinusoids will be presented. In the examples, the WD's will be processed through convolution in the frequency domain since this format conveys the frequency summing and difference effects well.

Before developing case I of the WD, equation (1) will be simplified into a convenient form representing convolution in the frequency domain. Taking the original equation and replacing $\tau/2$ with τ , gives

$$W(t, f) = \int z(t+\tau) z^*(t-\tau) e^{j2\pi f\tau} d\tau . \quad (2)$$

Note, with removal of $\tau/2$ from the WD equation, f now represents twice the actual frequency of spectral components contained in the original time signal. To simplify further evaluation, one should just consider one cross section of the WD at $t = t_o$

$$W(t_o, f) = \int z(t_o+\tau) z^*(t_o-\tau) e^{j2\pi f\tau} d\tau . \quad (3)$$

Letting

$$x(t) \equiv z(t_o+\tau)$$

$$y(t) \equiv z^*(t_o-\tau) .$$

Equation (3) can be viewed as the FT of the product $x(t)y(t)$

$$W(t_o, f) = FT\{x(t)y(t)\} . \quad (4)$$

The FT of the product $x(t)y(t)$ can also be viewed as a convolution in the frequency domain. Given that

$$x(t) \Leftrightarrow X(\alpha)$$

$$y(t) \Leftrightarrow Y(\alpha)$$

where \Leftrightarrow denotes FT pair.

Equation (4) can now be written as the convolution

$$W(t_o, f) = \int X(\alpha) Y(f - \alpha) d\alpha \quad (5)$$

This form of the WD will be used in the following graphical evaluations.

WD CASE I: ANALYTIC SIGNAL CONTAINING SINGLE SINUSOID

For this case, the real signal is a single sinusoid at frequency f_o

$$r(t) = \cos(2\pi f_o t) \quad .$$

The imaginary portion of the analytic signal, $z(t)$, is calculated through the HT of the real signal

$$i(t) = \text{HT}\{\cos(2\pi f_o t)\} = \sin(2\pi f_o t) \quad .$$

The analytic signal, $z(t)$, now becomes

$$z(t) = \cos(2\pi f_o t) + j \sin(2\pi f_o t) = e^{j2\pi f_o t} \quad .$$

The complex conjugate of $z(t)$ is

$$z^*(t) = e^{-j2\pi f_o t}$$

and

$$z^*(-t) = e^{j2\pi f_o t}$$

Moreover, the FT of both $z(t)$ and $z^*(-t)$ is a delta function shifted by f_o .

$$\text{FT}\{e^{j2\pi f_o t}\} = \delta(f - f_o)$$

This sample case is now in proper form with respect to equation (4), with

$$x(t) = z(\tau) \quad ,$$

$$y(t) = z^*(-\tau) \quad , \quad (t_o = 0)$$

and

$$X(f) = \delta(f-f_o)$$

$$Y(f) = \delta(f-f_o) .$$

With $t_o = 0$, equation (5) can be written as a function of frequency only

$$W(f) = \int X(\alpha) Y(f-\alpha) d\alpha , \quad (6)$$

and the WD for case I can now be developed graphically (fig. 1) through convolution in the frequency domain.

The left-hand side of figure 1 displays the translation of the $Y(-\alpha)$ spectrum during the convolution process defined by equation (6). The right-hand side of the figure shows successive contributions to the WD spectrum as the frequency, f , varies during the convolution. For this case involving the analytic signal of a single sinusoid, a contribution to $W(f)$ is made only when $f = 2f_o$. Remembering that f now represents twice the actual frequency of spectral components contained in the original time signal, f must be scaled by $1/2$ to yield a correct frequency value. In this case, the true frequency would be $2f_o/2$, or f_o , which is the expected result.

WD CASE II: ANALYTIC SIGNAL CONTAINING MULTIPLE SINUSOIDS

For this case, the real signal is composed of two sinusoids at frequencies of f_1 and f_2

$$r(t) = \{ \cos(2\pi f_1 t) + \cos(2\pi f_2 t) \}$$

This case is identical to WD case I except that the real signal contains two discrete components. Using the same method of reduction as in the previous case yields

$$X(f) = \delta(f-f_1) + \delta(f-f_2) ,$$

$$Y(f) = \delta(f-f_1) + \delta(f-f_2) .$$

Again, using equation (6), the WD for case II can be developed graphically (fig. 2) through convolution in the frequency domain.

As in figure 1, the left-hand side of figure 2 displays the translation of the $Y(-\alpha)$ spectrum during the convolution defined by equation (6), and, the right-hand side shows successive contributions to the WD spectrum as the frequency, f , varies. Since the original time signal contains multiple discrete components, peaks in the WD spectrum are generated when $f = 2f_1$ and $f = 2f_2$. Again, scaling by $1/2$ yields the correct frequency representations of the spectral components. However, in this case, the WD spectrum also exhibits a contribution at $f = f_1 + f_2$. This contribution is due to cross term coupling between the components at f_1 and f_2 . This coupling is displayed in figure 2 where the peaks b and c of the $X(\alpha)$ spectrum line up with peaks c and b of the $Y([f_1 + f_2] - \alpha)$ spectrum. This cross coupling effect contributes a peak to the WD spectrum at the frequency $[f_1 + f_2]$. After scaling, this false peak would appear in the WD spectrum at a frequency of $[f_1 + f_2]/2$.

Generation of false peaks due to cross coupling effects severely limits the practical application of the WD since few real world signals are single component. As shown in the previous

example, use of the conventional WD in developing time-frequency representations of multicomponent signals, even with the use of an analytic signal, introduces erroneous spectral components. These "phantom" peaks only confuse the resulting WD spectrum.

III. THE MODIFIED WIGNER DISTRIBUTION

In order for the WD to perform as a practical tool in the time-frequency analysis of multicomponent signals, unwanted erroneous spectral components due to cross coupling among both negative, and most notably, positive frequency components in these signals must be eliminated. The MWD accomplishes this. Thus, the superior time-frequency resolution of the WD can be attained without the generation of "phantom" spectral peaks.

For a cross section of the time-frequency representation of a real signal $r(t)$, at $t = t_o$, the MWD is introduced and is defined by:

$$M(t_o, f) = \int \mathbb{W}(\alpha - f/2) X(\alpha) Y(f - \alpha) d\alpha \quad , \quad (7)$$

where

$$x(t) \equiv r(t_o + t) \quad ,$$

$$y(t) \equiv r(t_o - t) \quad ,$$

and

$$X(f) \Leftrightarrow x(t) \quad ,$$

$$Y(f) \Leftrightarrow y(t) \quad .$$

As equation (7) suggests, the MWD is evaluated in the frequency domain using the FT's of a real time signal centered at t_o and its respective reversed signal also centered at t_o . The central trait of the MWD which separates the new technique from the traditional WD is its smart frequency window function, $\mathbb{W}(f)$. Use of this window function eliminates the cross coupling of positive frequency components. This in turn prevents erroneous spectral peaks from entering the MWD time-frequency representation during the evaluation of a multicomponent signal. Moreover, use of the smart window, $\mathbb{W}(f)$, eliminates cross coupling between positive and negative frequency components by preventing their interaction during the evaluation of the MWD. There are some limitations on the use of the smart window, and they will be discussed later. The MWD does not rely on the use of the analytic signal of the subject time signal; thus, the HT of the original time signal is no longer necessary. Finally, since the MWD is evaluated in the frequency domain, aliasing due to the frequency summing effect is avoided.

As with the WD, the evaluation of the MWD will also be illustrated graphically. Where the WD was reduced to a more convenient form representing convolution in the frequency domain to simplify its graphical presentation, the MWD is actually evaluated through convolution in the frequency domain. The graphical evaluations of MWD's which follow include the same two cases which were presented for the WD. MWD case I develops the spectrum for a real signal containing a single sinusoid while MWD case II evaluates a real signal containing multiple sinusoids.

Using equation (7), MWD cases I and II can be developed graphically through convolution in the frequency domain.

MWD CASE I: REAL SIGNAL CONTAINING SINGLE SINUSOID

The real signal to be evaluated is a single sinusoid at frequency f_o

$$r(t) = \cos (2\pi f_o t) .$$

The required time signals centered at t_o are

$$x(t) = \cos \{2\pi f_o(t_o+t)\} ,$$

$$y(t) = \cos \{2\pi f_o(t_o-t)\} .$$

To simplify the evaluation, let $t_o = 0$, yielding

$$x(t) = \cos \{2\pi f_o(+t)\} ,$$

$$y(t) = \cos \{2\pi f_o(-t)\} .$$

Fourier transformation of $x(t)$ and $y(t)$ gives $X(f)$ and $Y(f)$

$$X(f) = \delta (f-f_o) + \delta (f+f_o) ,$$

$$Y(f) = \delta (f+f_o) + \delta (f-f_o) .$$

$X(f)$ and $Y(f)$ are equivalent with both frequency representations consisting of two delta functions, one delta function being shifted along the positive frequency axis by f_o and the other shifted along the negative frequency axis by f_o . Using equation (7), the MWD for case I can be developed graphically (fig. 3).

Figure 3 is essentially the same as figure 1 which displays the development of the WD for a signal containing a single discrete component. However, since the MWD operates on real signals, the $X(\alpha)$ and $Y(\alpha)$ spectra also contain negative frequency components. Moreover, figure 3 introduces the smart window function, $\mathbb{W}(f)$. The window function is a gate in the frequency domain of unity amplitude which translates along the dummy variable (α) axis at one half the rate of the $Y(-\alpha)$ spectrum translation during the convolution. The window, as shown in figure 3, has a width in frequency of $2m$. This width parameter is almost inconsequential in the processing of single component signals such as in this case, but a proper window width is very critical in the evaluation of multicomponent signals. As previously stated, the window, $\mathbb{W}(f)$, eliminates cross coupling between positive and negative frequency components by preventing their interaction. Moreover, it eliminates interaction between components in a multicomponent signal. The window function's influence on a multicomponent signal will be discussed in MWD case II. For a single component signal, unwanted cross coupling would have contributed a false spectral peak at zero frequency; however, the gating action provided by the window function prohibits this coupling.

For this case involving a real signal containing a single sinusoid, a contribution to the MWD spectrum, $M(f)$, is made only when $f = 2f_o$. Notice, that when the $Y(-\alpha)$ spectrum has translated

along the α axis by $2f_o$, the window function, $\mathbb{W}(f)$ has translated by a frequency of one half of $2f_o$, or, f_o . This positioning of the window function permits the desired coupling which only provides a contribution to the MWD spectrum at $f = 2f_o$. Again, this f must be scaled by $1/2$ to yield a correct frequency value. This yields the expected frequency of f_o .

MWD CASE II: REAL SIGNAL CONTAINING MULTIPLE SINUSOIDS

In this case, the real signal consists of two sinusoids at frequencies of f_1 and f_2

$$r(t) = \{\cos(2\pi f_1 t) + \cos(2\pi f_2 t)\} .$$

This case is identical to MWD case I except that the real signal now contains two discrete components. Similar simplification as in the previous case yields the frequency representations of the time signals $x(t)$ and $y(t)$ with

$$X(f) = \delta(f-f_2) + \delta(f-f_1) + \delta(f+f_1) + \delta(f+f_2) ,$$

$$Y(f) = \delta(f+f_2) + \delta(f+f_1) + \delta(f-f_1) + \delta(f-f_2) .$$

With these frequency representations, the MWD for case II can be developed graphically (fig. 4) using equation (7).

As in the previous example, figure 4 shows how the positioning of the window function allows desired couplings which in turn make correct contributions to $M(f)$. These couplings result in peaks at the frequencies $2f_1$ and $2f_2$ in the final MWD spectrum. However, the key feature of the MWD, which separates it from the conventional WD, is its ability to eliminate the cross coupling of positive frequency components. This is shown in figure 4 when $f = f_1 + f_2$. At this value of f , notice that the components b and c of the $X(\alpha)$ spectrum line up with peaks c and b , respectively, of the $Y([f_1+f_2]-\alpha)$ spectrum. This is a graphic representation of cross coupling between positive frequency components. This cross coupling is eliminated by the positioning of the frequency window. Notice how the smart window is positioned between the components c and b in the $Y([f_1+f_2]-\alpha)$ spectrum thereby preventing cross coupling. In this situation, the width of the frequency window is critical since too wide a window would permit cross coupling. For this reason, the frequency resolution of the MWD in differentiating spectral peaks is governed by the window function, $\mathbb{W}(f)$. In figure 4, if $[f_2-f_1]$ were less than the window width, $2m$, cross coupling between positive frequency components would occur and erroneous peaks would be contributed to the MWD spectrum just as in WD case II.

IV. IMPLEMENTATION OF THE MODIFIED WIGNER DISTRIBUTION IN DIGITAL FORMAT

Before developing a digital representation of the MWD, its general form given by equation (7) will be simplified. Starting with equation (7)

$$M(t_o, f) = \int \mathbb{W}(\alpha - f/2) X(\alpha) Y(f - \alpha) d\alpha , \quad (7)$$

where

$$x(t) \equiv r(t_o + t) ,$$

$$y(t) \equiv r(t_o - t) ,$$

and

$$X(f) \Leftrightarrow x(t) ,$$

$$Y(f) \Leftrightarrow y(t) .$$

Again, equation (7) defines a cross section of $M(t, f)$ at $t = t_o$. By defining

$$\beta = (f/2) - \alpha ,$$

equation (7) becomes

$$M(t_o, f) = -\int \mathbb{W}(-\beta) X([f/2] - \beta) Y([f/2] + \beta) d\beta . \quad (8)$$

Letting $f' = (f/2)$ yields

$$M(t_o, f') = -\int \mathbb{W}(-\beta) X(f' - \beta) Y(f' + \beta) d\beta . \quad (9)$$

Since the window function is symmetric, $\mathbb{W}(-\beta) = \mathbb{W}(\beta)$ and equation (9) becomes

$$M(t_o, f') = -\int \mathbb{W}(\beta) X(f' - \beta) Y(f' + \beta) d\beta . \quad (10)$$

Finally, by letting $\gamma = -\beta$, and by invoking symmetry of the frequency window once again, the MWD representation becomes

$$M(t_o, f') = \int \mathbb{W}(\gamma) X(f' + \gamma) Y(f' - \gamma) d\gamma . \quad (11)$$

Note, that in this form, the MWD represents a frequency which no longer needs scaling. Moreover, equation (11) is in a form conducive to digital implementation. The digital form of equation (11) is

$$M(k) = \sum_{i=-m}^{+m} X(k+i) Y(k-i) , \quad (12)$$

where $X(k)$ is the discrete Fourier transform (DFT) of a subject real time series, $x(n)$, centered at t_o , and $Y(k)$ is the DFT of $y(n)$, the reversal of $x(n)$, also centered at t_o . $M(k)$ represents the discrete MWD spectrum of a time signal centered at t_o , and the summation limits in equation (12) constitute the smart window function. Since $y(n)$ is the reversal of $x(n)$, it can easily be proven that,

$$Y(k) = X^*(k) W_N^{-k} . \quad (13)$$

where

$$W_N \equiv e^{-j(2\pi/N)} .$$

N denotes the number of discrete values in the time history used in calculation of the spectrum with n serving as a position index. Finally, by combining equation (13) and (12), the final form of the digital representation of the MWD is attained

$$M(k) = \sum_{i=-m}^{+m} X(k+i) X^*(k-i) W_N^{-(k-i)} . \quad (14)$$

Equation (14) states that the evaluation of the MWD at frequency k is simply the sum of the left-hand side and right-hand side of a signal's FFT spectrum, $X(k)$, with both sides centered at frequency k , modified by a phase correction term of unity amplitude. Note, that when no window is applied ($m = 0$), the MWD reduces to a special form with an amplitude equal to the power spectral density (PSD) but modified by a phase term.

V. WIGNER AND MODIFIED WIGNER DISTRIBUTION EXAMPLES

In order to test the capability of the MWD in extreme situations, a simulated sine wave varying linearly in frequency at a rate of $\sim 400,000$ Hz/s was processed using both the traditional STFT method and the MWD. Figure 5 shows the STFT isoplot (logarithmic in amplitude) of a sine wave whose frequency first decreases then increases rapidly at this rate within 25 ms. The sampling frequency in this case is 10,240 Hz, and the length of the moving time window is 12.5 ms (corresponding to 128 discrete data points) with 20 Hanning windows applied. Use of the Hanning window makes the effective time window approximately 3 ms. As seen in figure 5, the STFT produces a very broad spectral peak since the frequency of the component varies considerably during each window. However, figure 6 shows the superior frequency resolution gained by the MWD (equation (14)) in processing the same simulated signal. Figure 7 shows the block of raw time data used in determining the first spectrum of the isoplots in figures 5 and 6. Along with this raw time signal, figure 7 also identifies the actual input simulated frequency at time 0.00625 s, the center of the first block of data. This frequency, 2,550 Hz, will serve as the benchmark in comparing the accuracy of the spectra generated by the STFT and MWD. Figure 8 shows the first spectra of figures 5 and 6 in linear format. The increased frequency resolution attained by the MWD is readily apparent. Moreover, the MWD is much more accurate in estimating the actual signal frequency at the center of the time window. While the STFT overestimated this frequency by 110 Hz, the MWD estimation was within 40 Hz. Again, this increased accuracy can be attributed to the frequency cancellation effect inherent to the MWD. Notice in figure 6 that, during the turn in frequency of the single component signal, lobing on the inside turn of the time-frequency representation becomes prominent since the frequency cancellation effect inherent to the MWD is limited during this extreme transitional period in which the signal is neither monotonically increasing or decreasing.

The isoplot of figure 9 has been developed through the STFT of a simulated sine wave whose frequency and amplitude both varied rapidly within the 400 ms of activity displayed. The length of the moving time window in the STFT is 25 ms with a sampling frequency of 10,240 Hz. Within the span of each time window, the frequency of the simulated sine wave changes approximately 300 Hz. For this reason, STFT of the signal produces a very broad spectral peak. Figure 10 shows the conventional WD spectrum for the same signal processed using the same parameters as the STFT. The increased frequency resolution relative to figure 9 is very evident. Figure 11 shows the corresponding MWD spectrum for the signal, which, in this case, provides just as much frequency resolution as the WD.

As shown in the previous figures, relative to traditional techniques, both the WD and MWD provide increased frequency resolution for a single component signal. However, this is not the case

in the evaluation of multiple components signals. Figure 12 shows the STFT isoplot of a simulated signal composed of two sine waves. As before, the frequencies and amplitudes of the discrete components are changing rapidly, and the corresponding spectral peaks are very broad. The WD spectrum for the same signal processed using the same parameters is shown in figure 13. With the multicomponent signal, the analysis form of the WD introduces an erroneous cross coupling component between the two simulated sine waves. This "phantom" peak train confuses the resulting time-frequency representation of the multiple component signal. Figure 14 is the corresponding MWD spectrum for the multicomponent signal. As can be seen in the figure, a high frequency resolution is attained (much improved over that of the STFT method) without unwanted cross coupling terms corrupting the time-frequency representation.

Figure 15 is a PSD isoplot showing the shutdown of an SSME alternate turbopump development (ATD) test rig following a component failure. As seen in the STFT isoplot, following the failure which occurs at 615 s into the test, the spectral distribution of the proximity probe signal becomes very noisy. In order to study the temporal and spectral characteristics of the signal just prior and following the failure, analysis focused on a very short time period around 615 s. Figure 16 shows the STFT isoplot for a 300-ms period extending from 615 to 615.3 s. No clear spectral characteristics can be identified in this time-frequency representation of the proximity probe measurement. Figure 17 is the MWD spectrum for the same period using identical processing parameters. While use of the traditional WD would introduce numerous erroneous spectral components in trying to improve upon the performance of the STFT, the MWD is successful in providing a much clearer time-frequency picture of the time signal without the "phantom" peaks.

As a final example, figure 18 is an "overlapped" (STFT) isoplot developed during the failure investigation of space shuttle main engine u/n 0215. During test 901-666, the engine experienced a premature cutoff due to a second-stage turbine-blade failure in the high pressure fuel turbopump (HPFTP) u/n 5602R1. The 0-1-kHz isoplot of figure 18 displays the time-frequency history of the fundamental shaft rotational (synchronous) frequency, N , as taken from an external pump-end accelerometer. As evidenced by the sudden increase in synchronous amplitude in the figure, the pump failure initiated at approximately 3.9 s into the test. The STFT and MWD isoplots for the pump speed transducer channel are shown in figure 19. The speed probe is a magnetic-type transducer which registers four "blips" with every revolution of the pump shaft, and, for this reason, the $4N$ component dominates both isoplots. Note the increased frequency resolution offered in the MWD plot of figure 19, especially during the ramp-down period following the failure. In order to attain more insight regarding the failure, attention was focused on the 100 ms timeframe surrounding the failure. Figure 20 shows the STFT and MWD isoplots for this extremely short period. Again, notice the increased frequency resolution offered by the MWD. Moreover, note the enhancement of the novel character of the frequency variation. The frequency separation exhibited in both plots at N , $2N$, $3N$, and $5N$ is currently interpreted as being caused by a phase discontinuity in these respective frequency components of the speed signal at the time of the failure. This phase discontinuity of the shaft precession can be attributed to the sudden turbine blade loss which instantaneously shifted the phase of the driving imbalance force. The frequency branching effect does not appear in the $4N$ component (which represents the pure shaft rotational motion, or motion other than precession) since the speed probe continues to count four "blips" per revolution regardless of the phase discontinuity at the time of the failure. It is also important to note that as a result of the branching (forking) of the frequencies, an artifact is present in the middle of the fork. This results because the difference between the upper and lower frequencies of the branch is within the bandwidth of the smart window.

ABSTRACT

Measurements on high performance rocket engine turbomachinery suffer from severe noise contamination associated with fluid flow, combustion processes, structural resonances, etc. It is thus extremely difficult to detect and discriminate between rotational system "signatures" and independent noise sources. In support of SSME development and advanced technology test programs, a number of sophisticated diagnostic algorithms have been developed and integrated into the signal processing system operational at MSFC's Structures and Dynamics Laboratory. These algorithms include higher order spectrum analysis, adaptive filtering, phase domain averaging, and other techniques applicable to specific SSME mechanical symptom detection and identification investigations.^{1,2}

This presentation reviews some recent developments in mechanical system detection and identification technology. The hypercoherence function was developed to detect the correlation between synchronous frequency characteristics and any *harmonic* component.^{3,4} The generalized hypercoherence,⁵ more recently applied, permits estimation of the nonlinear correlation between a selected frequency (e.g., shaft speed) and an *arbitrary* frequency component. A hypercoherence filtering algorithm is also described.^{6,7} A new signal processing tool (the Modified Wigner Distribution), which has proven useful in resolving time-frequency characteristics of highly nonstationary data typical of engine startup, cutoff, and throttling, is demonstrated.⁸ The technique effectively suppresses the spurious spectral peaks inherent with the standard Wigner spectrum for a signal with multiple frequency components. This paper briefly summarizes the analytical basis for the above algorithms. Practical application of the methods is then demonstrated through the evaluation of vibration measurements from SSME hot firing tests.

INTRODUCTION

Equipment failures are generally preceded by growing tolerances, imbalance, bearing element wear, and the like, which may manifest themselves through subtle modifications in the waveform observed by dynamic measurements. Conventional linear spectral analysis has long been used to identify the signal characteristics associated with machinery faults in vibration signature analysis. However, nonlinearities can play a significant role for signature identification. It has been observed that different rotational mechanisms may interact due to some nonlinear process.^{9,10,11} When this occurs, coherent phase relationships may exist, which can be identified from response signals. Frequency sum and difference components are one of the commonly observed nonlinear (quadratic) phenomena. A typical example is a synchronous (shaft rotational) frequency component modulated by subsynchronous whirl.² Other kinds of nonlinearity include high level harmonic content of synchronous vibration due to waveform clipping from rubbing.³ All these signals represent nonlinear phenomena since their spectral components at different frequencies are not independent of each other. Due to the lack of phase information, traditional spectrum analysis cannot identify such phenomena. Therefore, higher order spectral analysis is required. This analysis includes a hierarchy of cumulant spectra such as bicoherence, tricoherence, etc. Each technique can identify nonlinearities of different order in a random signal and be applied to the particular type of failure mechanism to be detected. The following discussion summarizes some of these techniques and applications. These methods are strictly appropriate to stationary time series. Spectral analysis of transient operational periods is addressed in the final section of this paper.

HIGHER ORDER SPECTRAL METHODS

THE BISPECTRUM AND BICOHERENCE

Given a stationary, zero mean process, the ordinary (linear) spectrum $S_{XX}(f)$, may be defined by

$$S_{XX}(f) = E[X(f) X^*(f)]$$

where $X()$ denotes the Fourier transform and $E[]$ is the ensemble average.

* Work performed under contracts NAS8-38156/-38095 with the National Aeronautics and Space Administration, Marshall Space Flight Center.

The next higher order is called the bispectrum $B_{XXX}(f_j, f_k)$.

$$B_{XXX}(f_j, f_k) = E[X(f_j) X(f_k) X^*(f_j + f_k)]$$

Succeeding terms can be written out following the permutation rules for higher order cumulants of random variables.¹²

The bicoherence, a normalized bispectrum, $b(f_j, f_k)$, is defined as

$$b_{XXX}(f_j, f_k) = \frac{|B_{XXX}(f_j, f_k)|}{\{E[|X(f_j)|^2] E[|X(f_k)|^2] E[|X(f_j + f_k)|^2]\}^{1/2}}$$

By Schwartz' inequality, it can be shown that the bicoherence is bounded by zero and unity. If the wave at $f_j + f_k$ is totally correlated to the waves at f_j and f_k , the bicoherence will equal unity. On the other hand, if these three waves or any one of them are statistically independent, the bicoherence will be zero.

APPLICATION OF BICOHERENCE

Bispectral analysis can be used to identify the existence of amplitude modulation (quadratic correlation) among spectral components. Enrich and Eshleman¹⁰ have described six analytical models to explain how these modulations may be physically generated. The bispectrum measures the degree of correlation by identifying phase relationship among three spectral components, i.e., frequency sum or difference. It has been applied to identify the quadratic phenomenon of a synchronous frequency component modulated by the cage frequency in a ball bearing and a synchronous component modulated by a 50-percent subsynchronous whirl frequency component.² As an example, Fig. 1a is the PSD of a vibration measurement taken on the turbopump on engine test 902-436. The peak marked "N" is the sync frequency component N and the peak marked "SS" is the suspected 52-percent subsynchronous whirl frequency component. There is also a component at synchronous frequency N plus SS. Notice that the level of SS component is not high enough to be of concern if it is due to independent sources. But it would be critical if it is a subsynchronous whirl component which is synchronous related. Therefore, it is important to be able to identify whether this SS component is synchronous related or not. Figure 1b shows one slice of bicoherence $b(w_1, 318.75 \text{ Hz})$ with the second frequency argument fixed at the subsynchronous frequency which is 318.75 Hz. Several peaks are detected, and the most significant peak is the one located at (N, SS; N+SS) which indicates that the SS and SS+N components are both synchronous related. Therefore, the 52-percent subsynchronous is really phase locking to the machinery rotational process and not a feedthrough from other sources.

Fig. 1: Power Spectrum and Bicoherence from Engine Test 902-436

THE TRICOHERENCE

The trispectrum can be used to identify cubic correlation among four spectral components. A special case of its application is to determine whether or not an apparent sideband structure is really due to modulation or not. Such a sideband structure is another commonly observed nonlinear defect signature. Figure 2a illustrates a preburner pump radial measurement during hot firing. Notice that even though the synchronous and overall RMS levels are nominal, an apparent sideband structure consisting of three peaks marked N-120, N, and N+120 is observed, which could indicate modulation of the synchronous frequency by a lower frequency component. Figure 2b shows a slice through the tricoherence by fixing two of the three independent frequency values. If the sideband and synchronous component are truly correlated, a peak would be expected at $f=N+120$. Since this does not occur, it indicates the sideband components are due to an independent source and are not synchronously related. In this case, an incorrect conclusion might be made based on the ordinary spectrum.

Fig. 2: Power Spectrum and Tricoherence from Engine Test FRF-26

HYPERCOHERENCE FUNCTIONS

THE HYPERSPECTRUM

To summarize the nonlinear interaction between harmonically related spectral components in a given stationary, zero mean signal, we define the *Hyperspectrum* of order n by the relation

$$H(n; f_1) = E[X^n(f_1) X^*(nf_1)], \quad n = 1, 2, 3, \dots$$

where f_1 is an arbitrary reference frequency, and nf_1 is an integer multiple of f_1 . Thus, the ascending terms in $H(n; f_1)$ represents a single value from the linear spectrum, bispectrum, trispectrum, etc, at the specific value $f_1 = f_2 = \dots = f_n$.

THE HYPERCOHERENCE

In analogy with the ordinary coherence function, we define the hypercoherence as a normalized hyperspectrum:

$$\Gamma^2(n; f_1) = \frac{|E[X^n(f_1) X^*(nf_1)]|^2}{E[|X^n(f_1)|^2] E[|X(nf_1)|^2]}, \quad n=1, 2, \dots$$

The hypercoherence function defines the nonlinear correlation between a reference frequency component in a vibratory signal and its harmonics. A major benefit is determination of whether an apparent harmonic in a complex vibration signal is correlated with the fundamental or caused by extraneous noise. The technique was applied to space shuttle main engine turbopump measurements. The linear spectra of two different tests appear virtually identical, other than the background noise (Figs. 3a and 3b). The PSD amplitudes at 3N frequency are very high for both tests. Figures 4a and 4b depict the hypercoherence functions computed for the same two test measurements. Figure 4a indicates that almost all the power at 3N is correlated with the rotational frequency component. On the other hand, the 3N component of the second test is due to a differing physical phenomenon not related to the rotational frequency. This indicates an improved degree of signature discrimination.

Fig. 3: Power Spectra from High Pressure Fuel Pump Measurements

Fig. 4: Hypocoherence Spectra

THE HYPERCOHERENCE FILTER

The above frequency analysis has been extended to a time-domain algorithm for the extraction of period signals in noisy data. The analytical basis for the techniques can be summarized briefly. Assume $X(t)$ and $Y(t)$ jointly periodic, with additive uncorrelated noise and (possibly coincident) periodic components. Let

$$X'(t) = F^{-1} [\sqrt{S_{XX}(nf_1)} \Gamma_X(n; f_1)]$$

$$Y'(t) = F^{-1} [\sqrt{S_{YY}(nf_1)} \Gamma_Y(n; f_1)]$$

$$n = 1, 2, 3, \dots$$

$$S = \text{Ordinary power spectrum}$$

$$\Gamma = \text{Hypercoherence function}$$

$$F^{-1} = \text{Inverse Fourier transform}$$

Now X' and Y' represent filtered time histories, and include only harmonics (nonlinearly) correlated with the common fundamental frequency. To generate an orbit plot or phase-plane representation of the two quantities, let

$$Y''(t) = Y'(t - \tau)$$

$$\tau = \phi / 2\pi f_1$$

$$\phi = \tan^{-1} [Q_{XY}(f_1) / C_{XY}(f_1)]$$

$$Q_{XY} = \text{Quadrature spectrum}$$

$$C_{XY} = \text{Cospectrum}$$

The time delay, τ , serves as a "key phasor," to initiate the relative phase angle between the two vectors. A phase-plane diagram of the filtered signals is thus obtained by plotting X' versus Y'' . The procedure is best illustrated by example. Figure 5a illustrates the orbit plot for two jointly periodic signals, each containing three harmonic components. Figure 5b represents the same plot when uncorrelated noise and independent, coincident periodic components have been added to each signal. This chaotic pattern is highly representative of hot firing data. Figures 5c and 5d are the recovered orbital diagrams by hypercoherence filtering and comb filtering, respectively. The superior performance of hypercoherence filtering is clearly indicated.

Figures 6a and 6b represent the filtered orbits from measurements at HPFT rad-90 degrees and rad-170 degrees during SSME tests 901-471 and 901-436, respectively. Figure 6a has a smooth orbital motion which represents a well-behaved rotational system. Figure 6b, however, indicates a potential rubbing problem. The two locations with sharp cusps appear to indicate possible impact between stationary and rotating system components.

GENERALIZED HYPERCOHERENCE

As discussed above, the spectral components to be identified by higher order spectra are required to satisfy certain frequency combinations (e.g., the sum of arguments is zero). However, in many situations, we wish to identify the correlation between two arbitrary frequency components that do not satisfy any such requirements. The generalized hypercoherence (GHC) was developed to deal with this situation. The GHC can identify the correlation between two arbitrary spectral components in the sense of frequency synchronization or lock-in.

To illustrate the approach, consider a gear train with gear ratio K . Coherent phase will exist between input and output rotational (spectral) components. When the gear ratio is an integer, the HC can identify their phase correlation. This is because the ambiguity introduced by the Riemann surface phase wrapping is within an integer multiple of 2π , which does not affect the coherence estimation. However, if the ratio is not an integer, phase wrapping will introduce a

Fig. 5: (a) Orbital Diagram of Noise-free Simulation, (b) Orbital Diagram of Simulation with Additive Gaussian White Noise, (c) Recovered Orbital Diagram by Hypercoherence Filtering, (d) Recovered Orbital Diagram by Using Comb

Fig. 6: a. Orbital Plot from Test 901-4T1 by Hypercoherence Filtering; b. Orbital diagram of 901-436

noninteger multiple of 2π , which yields ambiguous phase. Therefore, phase correlation cannot be uniquely identified in the phase domain. Based on this observation, the GHC was developed to identify such phase coherence by correlating the rate of change of phase, which is also called the instantaneous frequency. By taking the time rate of change of phase, the ambiguous term is eliminated, and the phase correlation is reflected in the frequency domain as frequency synchronization.

A vibration signal may be treated as an FM signal with different spectral components at different center (carrier) frequencies. Assume that there is some intelligence being frequency modulated in the signal as the instantaneous frequency about these carriers. To recover the intelligence, we demodulate the FM signal to estimate its instantaneous frequency signal. A narrow-band random process can be modeled as a sine wave with slowly varying amplitude $A(t)$ and phase $p(t)$:

$$x(t) = A(t) \cos [2\pi f_c t + p(t)]$$

The instantaneous frequency $f_i(t)$ is defined by:

$$f_i(t) = \frac{d p(t)}{d t}$$

A logic diagram illustrating the computational procedure is shown in Fig. 7.

Identification of composite modulation. The GHC technique was applied to identify a complicated modulation signal, the so-called "composite-modulation" phenomenon. It has been observed that modulation may exist between a harmonic of the shaft speed and a harmonic of a subsystem frequency without these harmonics showing up in the linear PSD. In such cases, direct (nonlinear) spectrum analysis is impractical. This composite-modulation phenomenon was observed in SSME vibration measurements associated with a bearing element defect as shown in Fig. 8. This PSD is taken from the SSME HPOP internal bearing strain gauge measurement during a hot firing test. The peaks marked N, 2N, 4N, etc., are the synchronous frequency component and its harmonics. The other peaks marked C and 2C are the bearing cage frequency components and are considered normal in such internal measurements. However, a strong anomalous component marked A is observed around frequency 8.5N. To assess this anomaly, we need to determine whether it is correlated with the cage or the sync frequency component.

By examining the frequencies of these components, it is observed that the 8.5N is equal to $14N-12C$, or $12(N-C) + 2N$. This implies that the 8.5N component might be caused by the modulation between the inner ball pass component (for a 12-ball bearing set), which is at frequency $12(N-C)$, and the second harmonic of SYNC at 2N. If the existence of such modulation can be proven, then the anomalous 8.5N component would represent a bearing-related signature. Thus, we can identify the composite modulation by simply matching the appropriate integer multiple of each instantaneous frequency signal corresponding to each modulating component. In this example, the carrier frequency of the FM demodulator is tuned to the cage frequency C, the SYNC frequency N, and the anomalous frequency A to generate their IF signal as shown in Figs. 9(a), (b), and (d). Figure 9(c) shows the summation of 12 times the IF signal of C and 14 times the IF signal of N. Theoretically, this composite IF signal should be equal to the IF signal at frequency $14N-12C$ due to modulation of 14N and 12C. Compare this to figure 9(d), which is IF of the anomalous component A. Strong correlation can be identified between them. Therefore anomaly A turns out to be SYNC- and cage-related component likely being generated from the modulation of the inner ball pass frequency at $12(N-C)$ and 2 times SYNC at 2N.

Fig. 9: Detection of Composite Modulation

NONSTATIONARY MODELS

Standard Fourier-based data analysis routines are based on the implicit assumption of a stationary time series. (The above techniques all require this assumption.) Turbomachinery components experience severe dynamic loads associated with highly transient operational periods of startup, shutdown, and engine throttling. A traditional tool for such analysis has been the short-time Fourier transform (STFT), which is obtained by applying a fixed-length moving time window to nonstationary data prior to performing the fast Fourier transform (FFT).¹³ However, if the spectral components within the signal vary considerably during the time window, the STFT often fails in providing enough frequency resolution to identify key time-frequency spectral characteristics. It is well known in the theory of functional analysis that an arbitrary square integrable function $x(t)$ can be decomposed into shifted and dilated versions of another square integrable function $g(t)$, called the analyzing wavelet, satisfies some additional conditions.¹⁴ This leads to the wavelet transform (WT).¹⁵ Having two free parameters available (a shift and a dilation), the WT offers greater flexibility than the STFT for modeling observed phenomena.

A third technique, called the Wigner distribution (WD) is capable of providing high resolution time-frequency estimates of nonstationary signals which are common in many fields, including the dynamic response of rotating machinery.^{16,17} Several obstacles arise in the direct use of the WD, particularly for signals with multiple spectral peaks. Most notable of these are aliasing and the generation of "phantom" spectral peaks in the resultant time-frequency distribution. A number of attempts, with varying degrees of success, have been employed to minimize these effects.^{18,19,20} The following discussion presents yet another approach. With the introduction of the "smart window," this approach will overcome these obstacles.⁸

THE MODIFIED WIGNER DISTRIBUTION

The WD is a powerful tool in determining the time-frequency characteristics of a highly nonstationary signal. The technique has been applied successfully in the identification of abnormal machine operating states through vibration signal analysis. Other applications include the analysis of time-varying spectra in optics, speech, sonar, and seismic signal processing.

The WD of a real signal $r(t)$ is given by

$$W(t, f) = \int z(t+\tau/2) z^*(t-\tau/2) e^{j2\pi f\tau} d\tau,$$

where $z(t)$ is the analytic signal of $r(t)$, $z(t) = r(t) + ji(t)$, and $i(t)$ is the Hilbert transform (HT) of $r(t)$, $i(t) = \text{HT}\{r(t)\}$. Therefore, the WD is the Fourier transform (FT) of the product between the original forward signal and corresponding backward signal both centered at time t .

In order to serve as a practical tool in the time-frequency analysis of multicomponent signals, unwanted erroneous spectral components due to cross coupling must be eliminated. The MWD accomplishes this. Thus, the superior time-frequency resolution of the WD can be attained without the generation of erroneous spectral peaks.

For a cross section of the time-frequency representation of a real signal $r(t)$, at $t=t_0$, the MWD is defined by

$$M(t_0, f) = \int W(\alpha - f/2) X(\alpha) Y(f - \alpha) d\alpha,$$

where

$$\begin{aligned} x(t) &\equiv r(t_0 + t) \\ y(t) &\equiv r(t_0 - t) \\ X(f) &\Leftrightarrow x(t) \\ Y(f) &\Leftrightarrow y(t) \end{aligned}$$

As the above suggests, the MWD is evaluated in the frequency domain using the FTs of a real time signal centered at t_0 and its respective reversed signal also centered at t_0 . The central trait of the MWD which separates the technique from the traditional WD is its smart frequency window function, $W(f)$. Use of this window function eliminates the cross coupling of positive frequency components. This in turn prevents erroneous spectral peaks from entering the MWD time-frequency representation during the evaluation of a multicomponent signal. Moreover, use of the smart window, $W(f)$, eliminates cross coupling between positive and negative frequency components by preventing their interaction during the evaluation of the MWD.

A digital recipe for extracting the MWD, given a discrete time series, is as follows:

$$M(k) = \sum_{i=-m}^{+m} X(k+i) X^*(k-i) W_N^{(k-i)}.$$

The above states that the evaluation of the MWD at frequency k is simply the sum of the left-hand side and right-hand side of a signal's FFT spectrum, $X(k)$, with both sides centered at frequency k , modified by a phase correction term of unity amplitude. Note that when no window is applied ($m=0$), the MWD reduces to a special form with an amplitude equal to the power spectral density (PSD) but modified by a phase term.

MWD APPLICATION

Figure 10 is an STFT isoplot showing the shutdown of an SSME alternate turbopump development (ATD) test following a component failure. In order to study the temporal and spectral characteristics of the signal just prior and following the failure, analysis focused on a very short time period around 615 s. Figure 10 shows the plot for a 300-ms period extending from 615 to 615.3 s. No clear spectral characteristics can be identified in this time-frequency representation of the proximity probe measurement. Figure 11 is the MWD spectrum for the same period using identical processing parameters. While use of the traditional WD would introduce numerous erroneous spectral components, the MWD is successful in providing a much clearer time-frequency picture of the signal without the "spurious" peaks.

Fig. 11: Modified Wigner Distribution During Shutdown

CONCLUDING REMARKS

The above discussion provides an overview of rocket engine diagnostic efforts in progress at MSFC. The technology is seen to be highly evolutionary. The effort is strongly driven by engine test observations, but the techniques should find wide application for dynamic data analysis and system identification. In conclusion, it is well realized that dynamic data assessment is but one of many necessary elements in the MSFC engine development and reliability improvement process.

CAVITATION DETECTION & MONITORING USING WIDE-BAND DEMODULATION SIGNAL

by: Jen-Yi Jong

[1] INTRODUCTION

A series of Inducer Test Leg (ITL) water flow tests were conducted to study cavitation phenomena in the water flow test facility at Marshall Space Flight Center (MSFC). From video taken during these tests, one can clearly visualize how cavitation develops and changes from one state to another, such as four-blade cavitation to alternate-blade cavitation. The signal from a vibration or high frequency pressure measurement also reflects such a cavitation condition change. However, in complicated operational conditions as experienced during flights or engine hot firing tests, these vibration signals will also contain elements induced by rotor-dynamics, structural dynamics, and hydrodynamics, which make it difficult to identify the failure sources when engine failure or malfunction occurs. Therefore, it is highly desirable to develop an effective method for cavitation detection and monitoring using vibration signal analysis when video information is not available.

The technique to be discussed in this section for cavitation detection and monitoring is based on a unique cavitation phenomenon reported in literature as:

"When cavitation occurs, the periodic rotational components (such as SYNC & its Harmonics) will amplitude modulate the wide-band high frequency noise generated from the collapse of cavitation bubbles."

Such a wide-band modulation phenomenon thus provides a unique signature in the high frequency region conducive to cavitation detection. However, conventional PSD analysis is unable to identify the signature associated with such a modulation phenomenon. In this section, the Wide Band Demodulation (WBD) signal method for cavitation detection will be discussed. Real test data from both inducer water test leg as well as Alternate Turbopump Development (ATD) E8 test stand will be used in demonstrating this WBD technique.

[2] WIDE-BAND MODULATION (WBM) SIGNAL

The signal model for Wide-Band Modulation can be represented as a sine wave multiplied by a noise signal $N(t)$:

$$x(t) = [1 + r \cos(Wrt)] N(t)$$

where $\cos(Wrt)$ represents a periodic motion, and $N(t)$ is zero-mean Gaussian White or Color Noise.

In signal processing literature, this type of signal is referred to as a "Cyclostationary signal". A special kind of periodicity exists in such a Cyclostationary signal. However, this periodic component is well hidden in the signal. An ordinary PSD will not show a discrete peak at the frequency of the periodic component. This can be easily deduced from studying its signal model. The operation between $N(t)$ and $\cos(Wrt)$ in the time domain is multiplication, but this multiplication becomes a convolution in the frequency domain. Since the PSD of noise is flat and that of a sine wave is a delta function, the convolution of these two PSD functions remains flat without any discrete peak. For this reason, a conventional PSD is unable to identify periodic components hidden within a Wide-Band Modulation signal.

[3] WIDE-BAND DEMODULATION (WBD) SIGNAL

In this section, three different methods for demodulating a WBM signal into a WBD signal are discussed. These are the tri-spectra method, the rectification method, and the Hilbert Transform envelope detection method. Simulation examples using an analytically generated signal will be used to demonstrate these wide-band demodulation processes.

Reference: "Fourth Order Spectra of Gaussian Amplitude-Modulated Sinusoids" Roger Dwyer, Navy Underwater System Center, Journal of Acoustic Society of America, August 1991.

In this reference, Dwyer proposes a special tri-spectral method to identify the existence of cyclostationary signals in underwater sonar signal processing. This tri-spectra is based on the Fourier Transform of a special auto-tri-correlation function $R_{xxxx}(T)$, which is defined as:

$$R_{xxxx}(T) = E[x(t) x(t) x(t+T) x(t+T)]$$

$$= E[x^2(t) x^2(t+T)] = R_{yy}(T)$$

$$\text{Where } y(t) = x^2(t)$$

The special tri-spectrum $T(W)$ is defined as the Fourier Transform of $R_{xxxx}(T)$. Notice that, the function $R_{xxxx}(T)$ reduces to the ordinary auto-correlation of $y(t)$, where $y(t)$ is defined as the square of the original signal $x(t)$. In other words, this special tri-spectrum is equal to the ordinary PSD of the square of the original signal. By examining the WBM signal model, it can be easily seen why such a simple square operation can recover the hidden periodicity in a WBM signal. The square of $x(t)$ can be written as:

$$x(t)^2 = [1 + r \cos(w_f t)]^2 [N(t)]^2$$

$$= [1.5 + 2r \cos(w_f t) + 0.5 r^2 \cos(2 w_f t)] [DC + N'(t)]$$

Terms Through Which Periodic Component Recovered

Where $N'(t)$ is defined by the following relationship:

$$[N(t)]^2 = [DC + N'(t)]$$

When squaring a zero-mean noise signal, a DC (mean value) component is introduced, and this DC component will be multiplied by the periodic component $\cos(W_f t)$. The resulting component then becomes superpositioned on the new noise component $N'(t)$. It is this new DC-introduced superpositioned term that allows the recovery of the periodic component hidden in the original WBM signal.

A simple simulation example will now be used to demonstrate this WBD process. Figure 1-a and 1-b show the respective time histories of simulated Gaussian White Noise (GWN) and a sine wave at 500 Hz. The time history $x(t)$ in figure 1-c is generated from multiplication of the GWN and the sine wave. The time history in figure 1-d is simply generated by the squaring of $x(t)$.

As discussed above, the ordinary PSD of $x(t)$, as shown in figure 2-a, does not show a discrete peak at the periodic frequency of 500 Hz. However, after squaring the signal, the DC-introduced superpositioned term generates a periodic component at 1000 Hz which is twice the periodic frequency of 500 Hz. This is how such a simple squaring operation is able to recover the hidden periodicity within a WBM signal.

[4] CAVITATION GENERATED WBM SIGNAL

The signal generated by cavitation can be modelled as the multiplication of two separate components $p(t)$ and $N(t)$:

$$x(t) = p(t) N(t)$$

Here, $N(t)$ represents the wide-band high frequency noise generated from the collapse of cavitation bubbles, while $p(t)$ represents the low frequency periodic pressure fluctuation due to the impeller rotational process. This pressure signal $p(t)$ contains a DC component due to its static pressure component P_{static} .

$$p(t) = [\underset{\text{DC}}{P_{static}} + P(t)_{dynamic}]$$

Therefore, a cavitation generated pressure signal is a typical WBM signal and is a good candidate for WBD processing. However, in most operational environments, the dynamic signal must be sampled at a much higher frequency than a regular dynamic analysis would require. This is because the PSD in the low frequency region always contains the fundamental Sync frequency component along with its harmonics ($2N$, $3N$, $4N...$), which are generated from the combination of all the effects of rotor dynamics, structural dynamics and hydrodynamics. These combinational effects make it difficult to isolate sources of vibration problems. However, when cavitation occurs, its signature should be contained in the noise floor of the high frequency region due to the uniqueness of wide-band modulation. The significance of this phenomenon is that the source of vibration can now be isolated to the hydrodynamic effects whose information is contained in the high frequency noise floor.

For cavitation detection, the high frequency raw signal must be high-pass filtered first to remove low-frequency discrete components while keeping the high frequency wide-

band noise data. WBD is then performed on this high-frequency noise floor data in order to recover any existing low frequency periodic component which is modulating the cavitation noise signal. As a result, a new low frequency WBD PSD is generated in addition to the original raw data PSD. However, unlike the raw data PSD which including multiple contributions from rotordynamics, structure dynamics and hydrodynamics, this new WBD PSD only reflects the hydrodynamic effect due to cavitation-generated modulation. If cavitation does not exist, the WBD PSD will reduces to regular broadband noise. However if cavitation does occur, the WBD PSD will show discrete peaks corresponding to the low frequency periodic rotational process modulating the collapsing bubble noise. This discussion is also depicted in figure 3.

Figures 4 shows three different algorithms for performing WBD. The first one shown in figure 4-(1) is the tri-spectrum method. The input raw wide-band high frequency signal is first high-pass filtered at some pre-determined cut-off frequency, then sent through a squaring operation, and then low-pass filtered. The PSD of the output signal is the special tri-spectral function $T(w)$. The original hidden periodicity within a WBM signal will now show up at its periodic frequency in the tri-spectra function. Figure 4-(2) shows the similar algorithm using the rectification method. Again, a WBM signal is high-pass filtered, then rectified, and low-pass filtered. Figure 4-(3) shows the Hilbert Transform method. Again, the input signal is first high-pass filtered, then Hilbert Transformed into an envelope signal which is then low-pass filtered. The PSD of the output signals from both figures 4-(2) and 4-(3) should identify the original hidden periodicity within the WBM signal.

[5] WBD SIGNAL FOR REAL TEST EXAMPLE

Real test data taken from 6 different accelerometers and pressure measurements across ATD LOX pump unit 3-1A during test E8-162 can be used to successfully demonstrate the WBD process. The inducer of this unit has four blades. Figure 5 shows the ordinary raw PSD corresponding to these six different measurements up to a maximum frequency of 5 KHZ. These PSDs all show the fundamental Sync frequency component and its harmonics. Figures 6 shows the ordinary raw PSDs of these 6 measurements with the maximum frequency increased to 50 KHZ. The discrete peaks are mostly concentrated in the low frequency region with some high frequency discrete line noise peaks also in the spectra. Notice that the signal in the wide-band high frequency noise floor is the prospective information to be used for cavitation detection. These high

frequency noise floors may contain just regular noise, or may have the very unique wide-band modulation phenomenon hidden within. Using the PSDs of both figures 5 and 6, one would not be able distinguish such a subtle difference.

The high frequency signals shown in figure 6 are first high-pass filtered at 20 KHz, after which their envelope signals are calculated through Hilbert Transform. Finally the envelope signals are low-pass filtered at 5 KHz. Figure 7 shows the resulting WBD PSDs of these 6 measurements. For the first five measurements, which include four accelerometers and one inducer outlet pressure measurement, no periodic component is recovered in the WBD signal. This indicates that the original wide-band high-frequency noise components of these five measurements are just ordinary noise signals with no modulation phenomenon present. However, in the sixth plot of figure 7, corresponding to the Three Quarter Chord Inducer Inlet Kistler pressure measurement, several strong discrete components show up in the WBD PSD. This indicates that wide-band modulation phenomenon indeed exists in the high frequency noise floor. In other words, cavitation is present in this test, and the rotational periodic components modulate with collapse bubble noise generating a unique WBM high-frequency noise floor. The demodulated WBD signal thus recovers these hidden discrete components.

Moreover an interesting phenomenon is present in this wide-band demodulation result. Notice that this WBD PSD of figure 7 has a strong 2N component and relatively weaker 1N, 3N and 4N components. Would this be an indication of an alternate-blade cavitation condition in which case cavitation bubbles only attach to two diagonally opposite blades of the four-blade inducer? In the following section, a WBD signal will be used not only to detect the presence of cavitation, but it will also allow us to monitor the condition of cavitation (i.e. four-blade or alternate-blade cavitation) as a function of time during test.

16] WBD SIGNAL FOR INDUCER TEST LEG WATER FLOW TESTING

In this section, WBD analysis for Inducer Test Leg (ITL) water flow test data is performed and cavitation condition predictions are compared to actual cavitation conditions visually monitored during the test. The actual cavitation conditions can be easily recognized in the video taken using a flow visualization device. Also in this testing, ordinary PSD already accurately reflect cavitation conditions since the testing is conducted in a laboratory environment which isolates the hydrodynamic effects. Therefore, the accuracy and effectiveness of the WBD signal for cavitation monitoring can best be verified using this water flow test data.

Figure 8 shows a regular PSD isoplot taken from a Kistler pressure measurement from Inducer Test Leg (ITL) Water Flow Test ITL-173. At the beginning of the test, one can clearly visualize from the video information that there are cavitation bubbles attached to each of the four inducer blades (four-blade cavitation). Then at a later time, around S+69s, two alternating bubbles out of the original four disappear. This indicates that the original four-blade cavitation condition has changed into alternate-blade cavitation. Later on at S+92s, the cavitation phenomenon totally disappears. This cavitation condition change is indeed accurately reflected by the raw PSD isoplot of figure 8. At the beginning of the test when the inducer is experiencing four-blade cavitation, the 4N PSD component is dominant. At S+69s, when the inducer begins experiencing alternate-blade cavitation, the 4N component diminishes while the 2N component starts to grow and dominate. Finally when all cavitation phenomenon disappears at S+92s, both the 2N and 4N components diminish. Therefore, in this particular case under isolated laboratory environment, the traditional raw PSD is already accurately monitoring the cavitation condition.

Figure 9-a and 9-b are the ordinary PSDs of the raw signal and high-pass filtered signal of the Kistler measurement with a maximum frequency 50 KHz. In this high-pass filtered version, all the low frequency discrete components under 5000 Hz are removed. WBD will be performed based on the wide-band high frequency noise floor of figure 9-b. Figure 10-a shows the 5 KHz raw data PSD at the beginning of the test, S+0s. The 4N component is dominant since the four bubble regions due to four-blade cavitation are generating a four pulse per revolution pressure fluctuation. Figure 10-b

shows the corresponding 5 Khz WBD PSD. This WBD PSD recovers several discrete components with the 4N component being the dominant one. This WBD PSD indeed correctly reflects the fact that the inducer is experiencing four-blade cavitation at the beginning of the test.

Figures 11-a and 11-b are the raw data and the WBD PSDs at S+69s when the four-blade cavitation changes into alternate-blade cavitation. The dominant peak of the WBD signal has now changed from 4N to 2N, which again correctly reflects actual cavitation condition changes the inducer experiences.

Figure 12 shows the corresponding PSD isoplot of the WBD signal. This time-frequency energy distribution agrees quite well with the regular raw data PSD isoplot and correctly monitors the cavitation condition change. However, when dealing with data from real world cases such as flight or hot firing tests rather than an isolated laboratory environment, a raw data PSD will reflect contributions from other effects (e.g. rotor and structural dynamics) other than just the hydrodynamic cavitation effects. These multiple contributions will make it difficult to identify the existence of cavitation or monitor cavitation condition changes. In this case, the WBD signal becomes an effective tool for cavitation monitoring.

[7] WBD SIGNAL FOR ATD E8 TEST

In this section, two different ATD E8 tests are discussed and analyzed using the WBD signal. In the first example (test E8-161), ATD HPOTP vibration levels are nominal. While during the test of the second example (test E8-162), an early test rig red-line cutoff occurred due to high synchronous vibration level. A WBD analysis is performed in order to determine if any significant discrepancy in the dynamic characteristics associated with cavitation condition existed between these two tests.

ATD TEST E8-161: NO HIGH SYNC VIBRATION CUTOFF

Figure 13 shows the raw PSD isoplot from Three Quarter Chord Inducer Inlet Kistler pressure measurement data taken during test E8-161. The time frame spans two different power levels, 104% and 111%. Throughout the test, the 4N component is dominant. However, immediately after the power level ramp up to 111%, the 2N

component starts to grow but remains smaller than the 4N component. Notice that, the 1N component was never really strong as compared to the 2N and 4N components.

Figure 14-a shows the composite RMS tracking time history of this Kistler measurement. The overall vibration level is getting stronger toward the end of the test. However, since the vibration level of the 1N component never exceeds the red-line level, early test rig cutoff never occurs in this test. Figure 14-b and 14-c show the raw PSD and band-pass filtered PSD of the Kistler transducer with a maximum frequency of 50 KHz. Information relating to the cavitation condition as experienced by the inducer is contained in the wide-band high frequency noise floor of figure 14-c, and will be recovered from the WBD signal.

Figure 15-a and 15-b are the 5 KHz raw and WBD PSDs of the Kistler measurement at 104% rated power level (RPL). The raw PSD picks up moderate N, 2N, 3N responses and a strong 4N component. Since the 4N component is the dominant component, the raw PSD indicates the possible existence of four-blade cavitation. Since the WBD PSD of figure 15-b clearly shows a dominant 4N component, it verifies that cavitation does exist and is indeed four-blade cavitation.

Figure 16-a and 16-b show the raw data and WBD PSDs at 111% power level. The raw data PSD picks up a weak N, a stronger 2N, and a dominant 4N component. It now becomes more difficult to identify whether the inducer is experiencing alternate-blade or four-blade cavitation just from this raw PSD. Since the WBD PSD only picks up a strong 2N component and some weak harmonics of 2N, cavitation has changed from a four-blade cavitation condition at 104% power level into an alternate-blade cavitation at 111% power level. This cavitation condition change is not at all obvious judging from its raw PSD. This is because other sources such as the ordinary linear 4N blade-passage pressure wave are corrupting the raw data. The WBD PSD isoplot in figure 17 clearly shows this cavitation condition change. Before the power level change, 4N is weak but is still the dominating one. But right after the power level change, the 2N component immediately takes over and becomes the strongest component.

Notice that there exist some similarities between the cavitation conditions of this E8-161 test and the Inducer Test Leg (ITL) water flow test example discussed in the previous section. In both of these tests, WBD PSD all present a dominant 4N

component as an indication of four-blade cavitation, and a dominant 2N component as an indication of alternate-blade cavitation. Another significant similarity is that the 1N component of their WBD PSDs was almost non-existent. Generally speaking, the regular raw PSD of a dynamic measurement will always pick up a relatively strong sync frequency component since 1N is the fundamental driving force in the dynamic system. A 1N presence in raw PSD data is considered to be normal unless its amplitude becomes too large. However, the presence of a sync frequency component in a WBD PSD would indicate an asymmetrical or unbalanced cavitation distribution. Such an asymmetric cavitation bubble distribution might create additional shaft unbalance forces and cause a high synchronous vibration.

ATD TEST E8-162: WITH HIGH SYNC VIBRATION INDUCED EARLY CUTOFF

During the ATD HPOTP test E8-162, early red-line cutoff occurred due to high level sync vibration. Figure 18 shows the raw PSD isoplot of the HPOTP Inducer Inlet Kistler measurement. The 4N component is clearly the dominant throughout the test. Originally the 1N component is relatively weak, but at around S+25.2s, its amplitude starts to grow rapidly and turns into a strong sync vibration ultimately leading to an early test rig cutoff.

Figure 19-a shows the composite RMS tracking time history from an ATD HPOTP strain gauge measurement. Right before the cutoff, there is a small jump in RMS amplitude directly followed by a rapid amplitude growth resulting in a high vibration cutoff of the test rig. Figure 19-b shows the high-pass filtered raw data PSD in which the wide-band high frequency noise floor is used for wide-band demodulation.

Figures 20-a and 20-b are the raw data and WBD PSDs of the Kistler measurement. Unlike the previous cases, a strong 1N component starts to show up in the WBD PSD. The presence of this strong 1N component is the most distinctive feature between this high-vib test and test E8-161 along with the ITL water flow test both without high synchronous vibration. The WBD PSD isoplot in figure 21 shows more clearly this cavitation condition change. Originally, the 2N component is dominant and is an indication of alternate-blade cavitation. Later on at S+23.5s, the 1N component starts to grow rapidly and then diminishes again. About half second later, high synchronous vibration occurs and leads to test rig cutoff. The cavitation-generated WBD signature

indeed shows some peculiar condition change right before the high-vib event. Whether this peculiar WBD signature change is directly related to the follow-on high synchronous vibration acting as a precursor is yet to be determined. Further research is currently in work.

[8] CONCLUDING REMARKS

When cavitation occurs, the periodic shaft rotational components will amplitude modulate the wide-band noise generated from collapsing cavitation bubbles. This wide-band modulation will make the periodic component become undetectable in the raw PSD of its dynamic measurement signal. However, this special phenomenon provides a unique signature for cavitation detection and monitoring. By using the WBD technique, the hidden periodicity can be recovered from a wide-band high frequency noise signal. The resulting WBD PSD can better indicate cavitation condition changes as compared to an ordinary raw data PSD. Some observations are summarized below:

- . Vibration data taken from Inducer Test Leg water flow tests have verified that such cavitation-generated WBM phenomenon does exist in its dynamic signal. In addition, the hidden periodicity recovered from its WBD signal correctly identifies the cavitation condition changes during the test.
- . Some similarities exist between the ITL water flow test and ATD test E8-161 of which neither experienced a high vibration cutoff. During these two tests, WBD PSDs show a dominant 4N component as an indication of four-blade cavitation and a dominant 2N component as an indication of alternate-blade cavitation. Most importantly, the WBD PSD 1N components for both tests are almost non-existent. A strong sync frequency component in a WBD PSD would indicate an asymmetrical or unbalanced cavitation distribution which generates additional shaft unbalancing force.
- . Unlike the cavitation conditions observed in water flow testing and the E8-161 test, a strong WBD PSD 1N component is observed during ATD test E8-162, in which strong synchronous vibrations led to an early test-rig red-line cutoff. This strong WBD 1N component is the most distinctive feature between this test with high sync vibration cutoff and those without cutoffs.

- . The WBD technique discussed in this section suffers from a severe limitation. Since the hidden periodicity is recovered from the envelope signal of a high frequency wide-band noise floor, any discrete components present in this high frequency region of the raw signal will generate false discrete peaks in the WBD signal pretending to be recovered hidden periodicities. This limitation may not be so critical in an isolated environment such as during laboratory testing where no discrete component shows up in high frequency region. But it would be a critical limitation in dealing with static firing of flight data in which many other vibration sources will contribute all kinds of high frequency components that corrupt the WBD signal. Attempts to remove such high frequency interference by using bandpass and adaptive filtering have been attempted. However, only a limited degree of success was achieved for a few simple cases. This procedure is tedious and inefficient, and it is difficult to be automated. Development of an efficient and effective method for wide-band demodulation without such a discrete-interference limitation is recommended for future research.

simulation signal $x(t) = GWN(t) \cos(F1 t)$ $F1=500$ Hz

simulation signal $x(t) = GWN(t) \cos(F1 t)$ $F1=500$ Hz
 $y(t) = x(t) * x(t)$

WIDE-BAND DEMODULATION

- . If no cavitation, PSD of WBD will be broadband noise
- . If cavitation occur, PSD of WBD will show discrete peaks corresponding to the low frequency periodic pressure fluctuation due to rotational process.

Anomaly Identification for Space Shuttle Main Engine Diagnostics

Jen Jong
Jess Jones, Preston Jones, Thomas Zolladz
Thomas Coffin

Turbomachinery fault detection and diagnosis represents a significant technical challenge in the aeronautics, transportation, and power industry. A reliable health monitoring system can prevent catastrophic failures and costly down time due to false alarms. As computer information processing technology continues to advance, the major challenge associated with machinery monitoring and diagnosis is shifting from how to obtain machinery vibration data to methods of information extraction and interpretation. Therefore, the incorporation of intelligent information processing capability has become invaluable to the machinery diagnostic process. Such an element can provide valuable dynamic information regarding the machine operational condition and greatly improve system reliability.

During the development of the Space Shuttle Main Engine (SSME), significant progress has been made in both the NASA and aerospace communities toward performance of the fault diagnostic function in instrumentation, modeling, and signal analysis techniques, in order to enhance the safety and reliability of Space Shuttle operations. A hierarchy of Anomaly Identification (AI) techniques for mechanical signature analysis has been developed to process and identify intelligent information hidden in a measurement signal which is often unidentifiable using conventional signal analysis methods. The AI methods can better identify well-hidden defect symptoms as well as false-alarm signatures. Within the SSME as well as other propulsion environments, dynamic measurements suffer from severe noise contamination associated with fluid flow, combustion processes, structural resonance, couplings, modulations, and other unknown mechanisms. Whenever an anomaly is detected, the AI function must determine if such anomaly is associated with a false-alarm or true defect signature. It will perform a detailed analysis and verification through the AI techniques. The ultimate effectiveness of this AI technology will depend upon its ability to optimally extract available machinery operational state information from a monitoring signal. A number of techniques have been developed and applied to SSME hot-firing test and flight data, and they appear to be highly promising for failure analysis and detection in other complex machinery applications.

Bi-spectral analysis is illustrated to identify the existence of amplitude modulation (quadratic correlation) among spectral components. The characteristics of such

quadratic interactions are usually reflected in its coherent phase relationship. It has been applied to identify the quadratic phenomenon of a synchronous frequency component modulated by the cage frequency components in a ball bearing system.

Tri-spectrum analysis identifies cubic correlation among four different spectral components. A special case of its application is to identify whether an apparent sideband structure is really due to modulation or not. Such a sideband structure is another commonly observed nonlinear defect signature. A typical example is a bearing cage frequency component periodically excites a structure mode at its natural frequency.

The hyper-coherence function was developed to detect the correlation between synchronous frequency characteristics and any harmonic component. A major benefit is to determine whether an apparent harmonic in a complex vibration signal is correlated with the fundamental or caused by extraneous noise. This analysis has been extended to a time-domain algorithm (hyper-coherence filtering) for the extraction of period signals in noisy data.

The generalized hyper-coherence, more recently applied, permits estimation of the nonlinear correlation between a selected frequency (e.g., shaft speed) and an arbitrary frequency component. The spectral components to be identified by higher order spectra are required to satisfy certain frequency combinations (e.g., the sum of arguments is zero). However, in many situations, we wish to identify the correlation between two arbitrary frequency components that do not satisfy any such requirements. The generalized hyper-coherence (GHC) was developed to deal with this situation.

A Modified Wigner Distribution has proven useful in resolving time-frequency characteristics of highly nonstationary data typical of engine startup, cutoff, and throttling. The technique effectively suppresses the spurious spectral peaks inherent with the standard Wigner spectrum for a signal with multiple frequency components.

This paper reviews some recent AI methodologies for mechanical fault detection and identification. We briefly summarize the analytical basis for the above algorithms. Practical application of the methods is then demonstrated through the evaluation of vibration measurements from SSME hot firing tests exhibiting anomalous behavior.

1.0 TECHNICAL DISCUSSION

This document is an updated version of a previously published report¹ on the vibration level statistics of the Phase II High Pressure Oxidizer Turbopumps (HPOTP) at different power levels. The purpose of this document was to evaluate if a significant change has occurred in the vibration statistics since the last report was published in November 1987.

Both the mean or average value and standard deviation do not indicate a significant change other than what would be expected from random chance for both the synchronous and composite vibration levels of the HPOTP. The updated version now includes 1217 measurements at the 100-percent power level, while the previous data base contained 429, or an increase of 788 in sample size. The average pump end vibration level changed from 1.33 Grms to 1.45 Grms, or 0.12, which is not considered significant. The standard deviation increased from 0.67 to 0.85, which also is not significant. On the turbine end measurements, the change was slightly less—from 1.23 to 1.28 Grms—with a change of the standard deviation from 0.56 to 0.68, which is also not significant. The composite levels, however, did indicate a slight decrease, which could be attributed to a decrease in the noise floor of the measurements. Additional analysis will be required to verify this hypothesis. A comparison of the calculated statistics in reference 1 is shown in Figures 1 through 4, with the updated statistics shown in Figures 5 through 8.

Again, for this study (for comparison with the reference 1 data base) only valid data from Phase II turbopumps that operated under normal conditions was included. Therefore, questionable data points (excessive noise, etc.), early cutoff, high running main impellers (0307 series of pumps), and pump S/N 2412 were deleted from this data base. However, including these pumps with the large data base presently available would still not significantly change the calculated statistics (mean and standard deviation). For studies that require information other than normal operational conditions (i.e., extreme values, higher moments, etc.), the complete data base should be utilized.

¹Swanson, W. L. "Statistical Analysis of Vibration Levels on the SSME Turbopumps; Volume I, Calculation of RMS Overlay Vibration Levels for the SSME Phase II High Pressure Oxidizer Turbopumps." Wyle Laboratories TM 68101-20, November 1987.

Section 2 contains plots of the cumulative distribution, probability density or histogram, and a table of the mean and standard deviation for each test stand. Power levels analyzed for this report include 65 percent, 100 percent, 104 percent, and 109 percent. Sufficient data was not available to perform a statistical analysis at 111 percent or the other power levels (i.e., 80 percent, 90 percent, etc.) although some data is available in the Diagnostic Data Base at these power levels. Section 3 contains plots of the FASCOS vibration levels (PBP 45-2, PBP 135-1, and PBP 135-3) utilized for flight vibration monitoring. The synchronous vibration levels are comparable to the RASCOS measurements, although FASCOS composite vibration levels are slightly lower since the cut-off filter is set at 800 Hz for these measurements, as opposed to 1000 Hz. A comparison of the RASCOS and FASCOS measurements are shown in Figures 9 and 10. The small differences noted from this study do not warrant any change in the overlay plots and/or green-run specifications for the SSME HPOTP at this time. Studies will continue on more sophisticated methods to evaluate the significance and/or comparison of data groups using recently received PC software (i.e., SYSTAT, IGOR, ETATALYZER).

Part IV: Statistical Analysis of Vibration Levels on the SSME Low Pressure Fuel Turbopumps

1.0 TECHNICAL DISCUSSION

This document is an updated version of a previous study of the vibration level statistics for the Low Pressure Fuel Turbopumps (LPFTP) at different power levels. The previous unpublished work was to evaluate the green-run specifications and establish an overlay plot for data evaluation comparison, including all LPFP and LPFT vibration data in the Diagnostic Data Base up to December 1987.

Figures 1 through 4 compare the previous vibration data with the data rolled into the data base from December 1987 to June 1990. No significant change is noted for the synchronous data groups. However, the composite levels, especially at 104% power level, may contain some outliers that will require further checking to ensure that a valid data base was utilized for the previous (December 1987) study. Figures 5 through 8 are the statistical data for the total data group, which is more applicable for comparison with future individual measurements and/or data groups.

Sections 2 and 3 contain plots of the synchronous and composite (50 to 1000 Hz) cumulative distribution, probability density or histogram, and a table of the mean, standard deviation for each individual measurement location for each test stand and data group. Section 4 is a listing of the present SSME Diagnostic Data Directory, and Section 5 contains plots and tabulations of the synchronous frequency versus power level calculated using the engine balance data.

1.0 TECHNICAL DISCUSSION

This document is an updated version of previously published reports^(1,2) on the vibration statistics of the Phase II High Pressure Oxidizer Turbopumps (HPOTP) at different power levels. The purpose of this document is to evaluate and document any significant change that has occurred in the vibration statistics since the last reports were published in November 1987 and June 1990. This report will also update and provide additional values (2N, 3N, 4N, etc) for overlay plots in the data analysis routines.

The first two moments—the mean (average value) and the standard deviation (variance)—do not indicate a significant change other than what would be expected from random chance for both the synchronous and composite (50-1000 Hz) vibration levels of the HPOTP. The updated version now includes 1796 measurements at the 100% power level, an increase of 579 from the June 1990 document. A comparison of the calculated statistics in references 1 and 2 are shown in Figures 1 through 6, with the updated statistics shown in Figures 7 through 11. The statistics for power levels at 63 percent and 64 percent and harmonics of synchronous (2N, 3N, and 4N) are also included in this document.

For the previous studies only valid data from Phase II turbopumps that operated under normal conditions were included in the data base analysis. Therefore, questionable data points (excessive noise, etc), early cutoff, high running main impellers and extreme outliers were not utilized. However, including these pumps or tests with the large data base presently available would still not significantly change the calculated statistics (mean and standard deviation). For studies that require information other than normal operational conditions (i.e., extreme values, higher moments, etc), the complete data base should be utilized. For this analysis, turbopumps with damping seals were defined as Phase II turbopumps since, during the development phase testing of the Phase II turbopumps, not all pumps contained the final design components during some of the tests.

Sections 2 through 8 contain plots of the cumulative distribution and probability density or histogram and a table of the mean and standard deviation for each test stand. The classical gamma function provides a convenient smoothing operation and computational method for evaluating the cumulative distribution of the data and is shown as an overlay on the plots. With the exception of one set of 4N plots and mean vibration levels below 0.5 Grms, the gamma distribution shows excellent fit to the measured data. At the low vibration levels, a smaller bin size should be used to analyze the data. Power levels analyzed for this report include 63 percent, 64 percent, 65 percent, 100 percent, 104 percent, and 109 percent. Sufficient data was not considered available to perform a statistical analysis at 111 percent or the other levels(i.e., 80 percent, 90 percent, etc.) although data is available in the Diagnostic Data Base at these power levels. Sections 7 and 8 contain plots of the FASCOS vibration levels (PBP RAD 45-2, PBP RAD 135-1, and PBP RAD 135-3) utilized for flight vibration monitoring. A slight increase from the previous study (approximately 0.25 Grms) was noted in the statistics for the composite FASCOS vibration levels (Figure 5). However, this is not considered significant since a much smaller increase (approximately 0.15 Grms) was noted for the synchronous levels (Figure 6). Studies will continue on

¹ Swanson, W. L. "Statistical Analysis of Vibration Levels on the SSME Turbopumps: Volume 1, Calculation of RMS Overlay Vibration Levels for SSME Phase II High Pressure Oxidizer Turbopumps." Wyle Laboratories technical memorandum TM 68101-20, November 1987.

² Swanson, W. L. "Statistical Analysis of SSME Turbopump Vibration Levels: Part I, High Pressure Oxidizer Turbopump." Wyle Laboratories technical note TN 60900-90-611, June 1990.

more sophisticated methods to evaluate the significance and/or compare different size data groups using recently received PC software (e.g., SYSTAT, IGOR statistical packages). Confidence intervals could be calculated based upon the Student t and Chi Square methods but are not included in this report. Additional study will be required to determine what degree of freedom applies to the data sample (number of pumps, with or without revisions, number of tests, total data sample, etc). Depending on the selection of the degree of freedom, a very wide variation can be obtained for the confidence interval, which places very little confidence in the confidence interval calculations.

Sections 9, 10, and 11 are included for reference. Section 9 is a listing of the tests, date of test, test duration, turbopump serial number, and the power levels where data is available from the Diagnostic Data Base program. Section 10 provides the synchronous frequency of the SSME turbopumps versus power levels, and Section 11 is a listing of the program written for calculation of the Gamma Cumulative Distribution Function. A bin size of 0.01 was used to calculate the 50%, 90% and 99% gamma values listed in Figures 7 through 11.

**STATISTICAL SUMMARY
OF SSME TURBOPUMP
VIBRATION LEVELS**

Part II
High Pressure Fuel Turbopump

by

Wayne L. Swanson

June 1992

FOREWORD

Wyle Laboratories' Engineering Division prepared this report for the National Aeronautics and Space Administration, George C. Marshall Space Flight Center. The work was performed under contract NAS8-38156, entitled "Data Analysis and Diagnostic Evaluation of Space Shuttle Main Engine Dynamic Measurements."

Technical direction, assistance, and maintenance of the Diagnostic Data Base computer program was provided by J. McBride and S. Gallik of MSFC/ED 23, with members of BCSS providing the computer output support. This is part II in a series of reports published and/or in preparation.

Statistical Summary of SSME Turbopump Vibration Levels

- Part I, High Pressure Oxidizer Turbopump
- **Part II, High Pressure Fuel Turbopump**
- Part III, Low Pressure Oxidizer Turbopump
- Part IV, Low Pressure Fuel Turbopump

Appendix: Historical Vibration Data Trend Analysis Test List and Cumulative Distribution Plots	

1.0 TECHNICAL DISCUSSION

This document is an updated version of previously published reports¹ on the vibration statistics of the Phase II High Pressure Fuel Turbopumps (HPFTP) at different power levels. The purpose of this document is to evaluate and document any significant change that has occurred in the vibration statistics since the last report was published in June 1990. This report will also update and provide additional values (2N, 3N, 4N, and PWLs) for overlay plots in the data analysis routines.

A comparison of the FASCOS vibration levels (HPFP RAD 0, HPFP RAD 174, and HPFP RAD 186) utilized for flight vibration monitoring are shown in Figures 1 and 2.

When compared to the previously published data² for the first two moments—the mean (average) and standard deviation (variance)—no significant change was noted except for what would be expected from random chance. Figure 1 shows the composite (50 to 1000 Hz) and Figure 2 shows the synchronous vibration levels.

An additional historical vibration data trend analysis was also performed for each year from 1987 to the first half of 1992. All available test data in the SSME diagnostic data base was grouped by pump and turbine end for each power level. Power levels at 100 percent, 104 percent, and 109 percent for the composite (50 to 1000 Hz) and synchronous were included in the analysis. The results of this study are shown in Figures 3 through 8. The most significant feature over the past one and a half decades is the steady decrease of the pump end vibration for both the composite and synchronous data. For the turbine end measurements, however, the change is much less and could be considered insignificant when factored by the number of data samples available in the early part of the program. Figure 9 more clearly illustrates the difference between the pump end and turbine end data trend at the 100% power level. Since all data was included in this analysis, the results should not be directly compared to the data from turbopumps under normal operation. The extreme outliers (obviously invalid data) was not included, however, but included was data from early cut-off tests, abnormal operation, etc. For future reference, the SSME diagnostic data plot output and test input list for each year are included as an appendix.

Figures 10 and 11 illustrate the type of analysis that can be easily performed using the data in the SSME diagnostic data base program. Note the very slight upward trend of the 1992 data when compared to 1991 and 1990. The distribution of the data plotted for each of the three years is shown in Figure 10, and a different type of plot format is shown in Figure 11. When compared to the previous years, the upward trend is insignificant since the data shift is only one bin (0.5 Grms) and approximately one half less data samples were available for 1992. Also, it can be noted that the mean value was not influenced by a series of higher than usual vibration levels for a series of tests and/or turbopumps.

The next analyses were performed to evaluate and update the values for overlay plots in the data analysis routines at additional power levels of 63 percent and 64 percent and the harmonics of synchronous (2N, 3N, and 4N). Selected as the start of the data set, was the point where the measurement scheme was changed to separate the RASCOS and FASCOS measurements, which will provide a consistent data set for the analysis. Also, the data set

¹Swanson, W. L. "Statistical Analysis of SSME Turbopump Vibration Levels: Part II, High Pressure Fuel Turbopump," Wyle Laboratories technical note TN 60900-90-611, June 1990.

²Ibid.

corresponds to the time period (1987) where the pump end measurements had stabilized to a reasonably constant level. Justification and/or validation for not using the total data set versus the data after 1987 is illustrated in Figure 12. The difference for composite vibration levels at 100% PWL is less than 0.6 Grms for the mean value and 0.8 for the standard deviation. Figures 13 through 17 include the 50%, 90%, and 99% values for the gamma distribution for the noted measurements. A bin size of 0.01 Grms was used to permit smooth plots and two-place tabulated values.

For the previous study,³ only valid data from high pressure fuel turbopumps that operated under normal conditions was included in the data base. The same criteria were applied for this analysis. Therefore, questionable data points (e.g., excessive noise), early cutoff, pseudo 3N (if identifiable), and extreme outliers were not utilized. Including these pumps or tests with the large data base presently available, however, would still not significantly change the calculated statistics (mean and standard deviation). For studies that require information other than normal operational conditions (i.e., extreme values, higher moments, etc), the complete data base should be utilized.

Sections 2 through 8 contain plots of the cumulative distribution, probability density or histogram, and a table of the mean and standard deviation for each test stand. The classical gamma function—shown as an overlay on the plots—provides a convenient smoothing operation and computational method for evaluating the cumulative distribution of the data. With the exception of isolated plots and mean vibration levels below 0.5 Grms, the gamma distribution shows excellent fit to the measured data. At the low vibration levels, a smaller bin size should be used to analyze the data. Power levels analyzed for this report include 63 percent, 64 percent, 65 percent, 100 percent, 104 percent, and 109 percent. Sufficient data was not considered available to perform a statistical analysis at 111 percent or the other levels (i.e., 80 percent, 90 percent, etc) although data is available in the diagnostic data base for these power levels. Sections 7 and 8 contain plots of the FASCOS vibration levels (HPFP RAD0, HPFP RAD 174, and HPFP RAD 186) utilized for flight vibration monitoring. From the previous study, a slight increase (approximately 0.25 Grms) was noted in the statistics for the composite FASCOS vibration levels (Figure 5). However, this is not considered significant since a much smaller increase (approximately 0.15 Grms) was noted for the synchronous levels (Figure 6). Studies will continue on more sophisticated methods of evaluating the significance and/or comparison of different size data groups using recently received PC software (i.e., SYSTAT, IGOR, and other statistical packages). Confidence intervals could be calculated based upon the Student t and Chi Square methods, but they are not included in this report. Additional study will be required to determine what degree of freedom applies to the data sample (number of pumps, with or without revisions; number of tests; total data sample; etc). Depending on the selection of the degree of freedom, a very wide variation can be obtained for the confidence interval, which places very little confidence in the calculations.

Sections 9, 10, and 11 are included for reference. Section 9 contains a list of the tests, date of tests, test duration, turbopump serial number, and the power levels, where data is available, from the diagnostic data base program. Section 10 contains a list of the program written for calculation of the gamma cumulative distribution function, and Section 11 provides the synchronous frequency of the SSME turbopumps versus power levels.

**STATISTICAL SUMMARY
OF SSME TURBOPUMP
VIBRATION LEVELS**

Part III
Low Pressure Oxidizer Turbopump

by

Wayne L. Swanson

June 1992

FOREWORD

Wyle Laboratories' Engineering Division prepared this report for the National Aeronautics and Space Administration, George C. Marshall Space Flight Center. The work was performed under contract NAS8-38156, entitled "Data Analysis and Diagnostic Evaluation of Space Shuttle Main Engine Dynamic Measurements."

Technical direction, assistance, and maintenance of the Diagnostic Data Base computer program was provided by J. McBride and S. Gallik of MSFC/ED 23, with members of BCSS providing the computer output support. This is part III in a series of reports published and/or in preparation.

Statistical Summary of SSME Turbopump Vibration Levels

- Part I, High Pressure Oxidizer Turbopump
- Part II, High Pressure Fuel Turbopump
- **Part III, Low Pressure Oxidizer Turbopump**
- Part IV, Low Pressure Fuel Turbopump

1.0 TECHNICAL DISCUSSION

This document is an updated version of a previously published report¹ on the vibration statistics of the Low Pressure Oxidizer TurboPumps (LPOTP) at different power levels. The purpose of this document is to evaluate and document any significant change that has occurred in the vibration statistics since the last report was published in June 1990. This report will also update and provide additional values (2N, 3N, 4N, and PWLs) for overlay plots in the data analysis routines.

Figures 1 through 3 compares the first two moments—the mean (average value) and the standard deviation (variance)—with the previous statistics for the LPOTP. No significant change is indicated other than what would be expected from random chance. Additional investigation will be required to explain the slightly lower mean value at 109-percent power level when compared to the 104-percent power level. The updated statistics are shown in Figures 4 and 5 for power levels at 63 percent, 64 percent, 65 percent, 100 percent, 104 percent, and 109 percent. The mean, standard deviation; one sigma; three sigma; and 50%, 90%, and 99% gamma are included. An interpretation of the gamma function at 50 percent is half the data should fall above and half below the listed value. For 90 percent, 10 percent of the data are expected to be above and 90 percent below the listed value. Other percentage point can be easily calculated using the program listed in section 8. This type of interpretation for the sigma values is much less accurate since the discrete gamma cumulative distribution function provides a much better fit to the measured data than a normal or Gaussian distribution.

For the previous study,² only valid data from low pressure oxidizer turbopumps that operated under **normal** conditions was included in the the data base analysis. Therefore, questionable data points (e.g., excessive noise), early cutoff, and extreme outliers were not utilized. Including these pumps or tests with the large data base presently available, however, would not significantly change the calculated statistics (mean and standard deviation). For studies that require information other than normal operational conditions (i.e., extreme values, higher moments, etc), the complete data base should be utilized.

Sections 2 through 6 contain plots of the cumulative distribution, probability density or histogram, and a table of the mean and standard deviation for each test stand. The classical gamma function—shown as an overlay on the plots— provides a convenient smoothing operation and computational method for evaluating the cumulative distribution of the data. For this study, the bin size was changed to 0.20 Grms from the normally used bin size of 0.50 Grms. In most cases, the gamma function provides an excellent fit to the data. Power levels analyzed for this report include 63, 64, 65, 100, 104, and 109 percent. Sufficient data was not available to perform a statistical analysis at 111 percent or the other levels (i.e., 80 percent, 90 percent, etc) although data is available in the diagnostic data base at these power levels.

Sections 7, 8, and 9 are included for reference. Section 7 contains a list of the tests, date of tests, test duration, turbopump serial number, and the power levels, where data is available, from the diagnostic data base program. Section 8 contains a list of the program

¹Swanson, W. L. "Statistical Analysis of SSME Turbopump Vibration Levels: Part III, Low Pressure Oxidizer Turbopump," Wyle Laboratories technical note TN 60900-90-611, June 1990.

²Ibid.

written for calculation of the gamma cumulative distribution function. A bin size of 0.01 Grms was used to calculate the 50%, 90%, and 99% gamma values listed in Figures 4 and 5. Section 9 provides the synchronous frequency of the SSME turbopumps versus power levels.

**STATISTICAL SUMMARY
OF SSME TURBOPUMP
VIBRATION LEVELS**

Part IV
Low Pressure Fuel Turbopump

by

Wayne L. Swanson

June 1992

FOREWORD

Wyle Laboratories' Engineering Division prepared this report for the National Aeronautics and Space Administration, George C. Marshall Space Flight Center. The work was performed under contract NAS8-38156, entitled "Data Analysis and Diagnostic Evaluation of Space Shuttle Main Engine Dynamic Measurements."

Technical direction, assistance, and maintenance of the Diagnostic Data Base computer program was provided by J. McBride and S. Gallik of MSFC/ED 23, with members of BCSS providing the computer output support. This is part II in a series of reports published and/or in preparation.

Statistical Summary of SSME Turbopump Vibration Levels

- Part I, High Pressure Oxidizer Turbopump
- Part II, High Pressure Fuel Turbopump
- Part III, Low Pressure Oxidizer Turbopump
- **Part IV, Low Pressure Fuel Turbopump**

1.0 TECHNICAL DISCUSSION

This document is an updated version of a previously published report¹ on the vibration statistics of the Low Pressure Fuel TurboPumps (LPFTP) at different power levels. The purpose of this document is to evaluate and document any significant change that has occurred in the vibration statistics since the last report was published in June 1990. This report will also update and provide additional values (2N, 3N, 4N, and PWLs) for overlay plots in the data analysis routines.

Figures 1 through 4 compare the first two moments—the mean (average value) and the standard deviation (variance)—with the previous statistics for the LPFTP. No significant change is indicated as shown in Figure 5, other than what would be expected from random chance. The updated statistics are shown in Figures 6 through 9 for power levels at 63, 64, 65, 100, 104, and 109 percent. The mean, standard deviation; one sigma; three sigma; and 50%, 90%, and 99% gamma are included. An interpretation of the gamma function at 50 percent is half the data would be expected to fall above and half below the listed value. For 90 percent, 10 percent of the data should be above and 90 percent below the listed value. Other percentage point can be easily calculated using the program listed in section 8. This type of interpretation for the sigma values is difficult since the distributions are skewed. The discrete gamma cumulative distribution function provides a much better fit to the measured data than a normal or Gaussian distribution.

For the previous study,² only valid data from low pressure fuel turbopumps that operated under normal conditions was included in the the data base analysis. The same criteria were applied for this analysis. Therefore, questionable data points (e.g., excessive noise), early cutoff, and extreme outliers were not utilized. Included were the 2218, 4001, 9105 and 82106 series of turbopumps, which have a history of above normal vibration levels at some measurement locations. Including or not including these pumps or tests with the large data base presently available does not significantly change the calculated statistics (mean and standard deviation).

Sections 2 through 6 contain plots of the cumulative distribution, probability density or histogram, and a table of the mean and standard deviation for each test stand. The classical gamma function—shown as an overlay on the plots—provides a convenient smoothing operation and computational method for evaluating the cumulative distribution of the data. In most cases, the gamma function provides an excellent fit to the data. Power levels analyzed for this report include 63 percent, 64 percent, 65 percent, 100 percent, 104 percent, and 109 percent. Sufficient data was not available to perform a statistical analysis at 111 percent or the other levels (i.e., 80 percent, 90 percent, etc) although data is available in the diagnostic data base at these power levels.

Sections 7, 8, and 9 are included for reference. Section 7 contains a list of the tests, date of tests, test duration, turbopump serial number, and the power levels, where data is available, from the diagnostic data base program. Section 8 contains a list of the program written for calculation of the gamma cumulative distribution function. A bin size of 0.01 was used to calculate the 50%, 90%, and 99% gamma values listed in Figures 6 through 9

1.0 INTRODUCTION

The purpose of this study was to determine an equation for the calculation of the synchronous frequency of the ATD High Pressure Oxidizer Turbopump (HPOTP) vs. power level. This equation will be utilized in the Dynamic Analysis Programs which allows the computer to seek the synchronous frequency in a predetermined band of frequencies. The data for this study was obtained from the MSFC Dynamic Data Base Computer program. All calculations and plotting were performed on a Macintosh IIfx using KaleidaGraph software. The static firing test numbers, turbopump serial numbers, power level profile and output data sheets are included as enclosures for future reference.

2.0 DISCUSSION

Sixty-three static firing tests were available in the Diagnostic Data Base for analysis at power levels of 65%, 90%, 100%, 104%, and 109%. A quick review of the plotted data in Enclosure 1 indicates we do not have a consistent data set. The first five plots are the synchronous frequency at the different power levels as listed in the data base. At all power levels except the 65% an increase in the frequency is noted. The next five plots are histograms which clearly show a multiple modal distribution which indicates there is a marked difference in the turbopump builds or operational rotational speed. After discussion with ED-23 personnel, five turbopump builds were chosen which appear to represent the final ATD HPOTP configuration and operational synchronous frequencies. The serial numbers of the turbopumps are:

8003R6, 7, 8
8107R1, 2, 3, 4
8202R1, 2, 3
8106R4
8105R5

This provided a total of 28 static firing tests for the analysis. However, not all power levels were run on each test, therefore less than 28 data samples were available at each of the different power levels.

3.0 RESULTS

Figure 1 shows that a linear curve-fit equation will provide the necessary accuracy for synchronous frequency vs. power level (in percent) for the ATD HPOTP. The equation is:

$$\text{Syn Freq} = 98.691 + 2.788 * \text{Pwl} \quad (1)$$

The calculated mean synchronous frequencies with the 3 Sigma values are shown in Table I and plotted in Figures 2 and 3 for each power level.

TABLE I

PWL %	Synch (Mean)	-3 Sigma	+3 Sigma
65	280	277	283
90	350	337	362
100	377	365	390
104	389	380	397
109	403	394	411

Figures 4 to 8 are the histograms and a comparison to the normal or Gaussian distribution at each power level. Considering the small sample size available for analysis, it appears a normal distribution can be assumed as a best fit to the data. The mean, standard deviation, minimum, maximum and number of data samples at each power level are listed on the plots. When more test data becomes available, additional analysis should be performed to verify the adequacy of equation 1 to determine the synchronous frequency vs. power level.

1.0 INTRODUCTION AND SUMMARY

The purpose of this study was to evaluate if the classical gamma distribution function previously utilized for the Rocketdyne Space Shuttle Main Engines (SSME) Turbopumps is applicable to the P&W ATD High Pressure Oxidizer Turbopump (HPOTP) measured vibration data. Classical distribution functions provide a convenient smoothing operation and computational method for evaluating the cumulative and density distribution and measured data. The application is desirable for data characterization since this permits continuous statistical definition and manipulation from discrete measurement observations. Density plots are useful for an assessment of the historical data scatter or dispersion around the mid-point or mean value. The three classical functions in this study include the gamma, Weibull, and normal (gaussian) distributions. To check the functions for goodness-of-fit, the total mean-square error was calculated for each function for the ATD PBP RAD vibration measurements. The data from the Diagnostic Data Base for this study was the composite (50-1000 Hz) and synchronous Grms levels at 100% power level.

Other classical and more robust methods are available to evaluate the fit of distribution functions to measured data but were not utilized for this study since a visual analysis in many cases is adequate. A visual review of the plots (Figures 1 to 4) shows the discrete gamma function provides the best fit to the measured ATD HPOTP and Rocketdyne turbopump vibration data. (Ref. 1 to 4) The gamma distribution function also has the least mean-square error for both the composite and synchronous vibration levels. It is therefore recommended the gamma distribution be utilized for smoothing and evaluation of the P&W ATD HPOTP vibration data.

2.0 GAMMA DISTRIBUTION

The gamma distribution contains two parameters related to the mean and standard deviation and is defined as follows (ref. 6):

$$f(x) = \frac{\lambda}{\Gamma(r)} (\lambda x)^{(r-1)} e^{-\lambda x} \quad x \geq 0 \quad (1)$$

where $\Gamma(r)$ is the gamma, or generalized factorial, function and $r, \lambda > 0$.

The parameters λ and r , in terms of the mean \bar{x} and variance (σ^2) are

$$\bar{x} = \frac{r}{\lambda}, \quad \sigma^2 = \frac{r}{\lambda^2} \quad (2)$$

Solving each equation for r ,

$$r = \bar{x}\lambda, \quad r = \sigma^2\lambda^2 \quad (3)$$

$$\text{or } \lambda^2\sigma^2 = \lambda\bar{x} \quad (4)$$

$$\lambda = \bar{x}/\sigma^2 \quad (5)$$

From the first equation of 2 and equation 4

$$\bar{x} = \frac{r \sigma^2}{\bar{x}} \quad (6)$$

$$\text{so } r = \frac{\bar{x}^2}{\sigma^2} \quad (7)$$

Using equations 1, 5, and 7,

$$f(x) = \frac{\bar{x}}{\sigma^2 \Gamma(\frac{\bar{x}^2}{\sigma^2})} \left[\frac{\bar{x} x}{\sigma^2} \right]^{(\bar{x}^2/\sigma^2 - 1)} e^{-\bar{x}x/\sigma^2} \quad (8)$$

Some important relationships of the gamma function are

$$\Gamma(n+1) = \int_0^{\infty} x^n e^{-x} dx \quad (9)$$

which leads to

$$\Gamma(n) = (n-1) \Gamma(n-1) \quad (10)$$

$$\Gamma(n) = (n-1)! \quad (11)$$

$$\Gamma(n+1) = n! \quad (12)$$

thus, the definition as a generalized factorial function.

For digital computation of the gamma term, the following polynomial approximation was used from reference 7.

$$\ln \Gamma(z) \sim \left(z - \frac{1}{2}\right) \ln z - z + \frac{1}{2} \ln 2\pi + \frac{1}{12z} - \frac{1}{360z^3} + \frac{1}{1260z^5} - \frac{1}{1680z^7} \quad (13)$$

Therefore, in terms of the mean Grms and standard deviation, the gamma probability distribution function is

$$f(x) = \frac{m}{s^2 \Gamma(m^2/s^2)} * \left[\frac{mx}{s^2}\right]^{(m^2/s^2-1)} * e^{-[mx/s^2]} * \Delta x \quad (14)$$

m = mean Grms level
s = standard deviation
 Δx = step size

Although the gamma distribution appears to provide a reasonable fit to the data, some additional improvements could be investigated. These include a change in the class interval width, unequal class intervals, and some type of truncated gamma to account for the low synchronous values approaching the noise floor of the measurement instrumentation system. It may be noted, $F(x)$ and $f(x)$ are not the continuous form of the cumulative probability function and probability density function but represent percentiles within discrete class intervals. This formulation permits direct comparison between classical function approximations and discrete frequency distributions representing empirical measurement characteristics.

3.0 WEIBULL DISTRIBUTION

The Weibull distribution is frequently used as a time-to-failure model. Its probability density function, from reference 6, is

$$f(x) = \left(\frac{\alpha}{\beta}\right) \left(\frac{x}{\beta}\right)^{\alpha-1} \exp \left[-\left(\frac{x}{\beta}\right)^\alpha\right], \quad x \geq 0, \alpha > 0, \beta > 0 \quad (15)$$

where β is the scale parameter and α is the shape parameter. The cumulative Weibull distribution is

$$F(x) = \int_0^x \left(\frac{\alpha}{\beta}\right) \left(\frac{x}{\beta}\right)^{\alpha-1} \exp \left[-\left(\frac{x}{\beta}\right)^\alpha\right] dx \quad (16)$$

$$= 1 - \exp \left[-\left(\frac{x}{\beta}\right)^\alpha\right], \quad x \geq 0 \quad (17)$$

The two parameters α and β in terms of the mean and variance are

$$m = \beta \Gamma \left(\frac{1}{\alpha} + 1\right) \quad (18)$$

$$s^2 = \beta^2 \left\{ \Gamma\left(\frac{2}{\alpha} + 1\right) - \Gamma^2\left(\frac{1}{\alpha} + 1\right) \right\} \quad (19)$$

where m = mean and s = standard deviation.

A closed form solution is not available for the nonlinear equations and the system must be solved by iteration. Define $g(\alpha)$ and $h(\alpha)$ in terms of the mean and standard deviation, then from equations 18 and 19,

$$\frac{m}{s} = \frac{\Gamma\left(\frac{1}{\alpha} + 1\right)}{\left[\Gamma\left(\frac{2}{\alpha} + 1\right) - \Gamma^2\left(\frac{1}{\alpha} + 1\right)\right]^{1/2}} = g(\alpha) \quad (20)$$

and, from equation 18,

$$\frac{m}{\beta} = \Gamma\left(\frac{1}{\alpha} + 1\right) = h(\alpha) \quad (21)$$

Iteration of equation 20 on α will provide the value of α when $g(\alpha)=m/s$ and β follows immediately from the numerator and equation 21.

$$\beta = \frac{m}{h(\alpha)} \quad (22)$$

The probability density and cumulative functions are then calculated from equations 15 and 17 using the α and β values of equations 20 and 22.

The fit of the Weibull distribution to the composite levels could be greatly improved by taking into account an arbitrary origin. Introducing the location parameter μ of 0.5 or 1.0 to account for the noise floor below which the values cannot fall and using the three-parameter Weibull probability density function defined as follows

$$f(x) = \frac{\alpha}{\beta} \left(\frac{x-\mu}{\beta} \right)^{\alpha-1} \exp \left[-\left(\frac{x-\mu}{\beta} \right)^{\alpha} \right] \quad (23)$$

which should shift the function to the right and provide a better fit to the data.

4.0 NORMAL (OR GAUSSIAN) DISTRIBUTION

The normal distribution is a frequently used statistical model. Its probability distribution function is

$$f(x_i) = \frac{1}{\sigma\sqrt{2\pi}} \exp \left[-\frac{(x_i-\mu)^2}{2\sigma^2} \right] \Delta x \quad (24)$$

where m and s are location and scale parameters, respectively, of the distribution. It should be noted that all normal distributions are symmetric and have the same shape—that is, the distribution has no shape factor. The cumulative normal distribution is

$$F(x_i) = \int_{-\infty}^{x_i} \frac{1}{\sigma\sqrt{2\pi}} \exp \left[-\frac{(x_i-\mu)^2}{2\sigma^2} \right] dx \quad (25)$$

The two parameters of the normal distribution are the mean and standard deviation. Using the previous notation, the probability distribution function is

$$f(x) = \frac{1}{s \sqrt{2\pi}} \exp \left[-\frac{(x-m)^2}{2s^2} \right] \Delta x \quad (26)$$

with the cumulative distribution calculated using $F(x) = \sum_{i=1}^N f(x)$. (27)

5.0 MEAN-SQUARE ERROR

The mean-square error was defined as

$$\text{MSEG} = \sum_{i=1}^B (G_i - \text{Grms}_i)^2 \quad (28)$$

$$\text{MSEW} = \sum_{i=1}^B (W_i - \text{Grms}_i)^2 \quad (29)$$

$$\text{MSEN} = \sum_{i=1}^B (N_i - \text{Grms}_i)^2 \quad (30)$$

B = Number of bins

G_i = Gamma function

W_i = Weibull function

N_i = Normal function

Grms_i = Measured data (percent) with bin width of 0.5

6.0 TECHNICAL DISCUSSION

A study to evaluate the vibration statistics of the ATD HPOTP for overlay plots in the test data analysis routines will utilize a classical distribution for calculation of the values. The overlay values will represent the ATD flight configuration when operating under normal conditions. Therefore, questionable data points (excessive noise, etc.) and extreme outliers will not be utilized for the overlay plot study. The same methodology was applied before the final comparison of the classical distributions to the measured ATD HPOTP vibration data. An illustration of the requirement to purge the data base of outliers is shown in Enclosure 1 for the composite and synchronous vibration levels at the 100% power level (PWL). The data values indicated as invalid were not included in the final analysis. It should be noted that even with the relatively small data sample, the invalid data points do not significantly effect the mean, but show a significant change in the higher moments (standard deviation, skewness, and kurtosis).

The computer program written in QuickBasic language is listed in Enclosure 2 and was utilized for all the classical distribution calculations. For future reference and cross checking, the composite vibration levels are included in Enclosure 3 with the synchronous vibration levels for this study extracted from Enclosure 3 of Reference 5.

Figures 5 to 8 are included for comparison of the vibration statistics and calculated gamma distribution of the Rocketdyne HPOTP. These plots were extracted from Reference 3 and illustrate the close fit the gamma distribution function provides for a larger data sample. A first-cut comparison between the P&W ATD and Rocketdyne HPOTP synchronous and composite vibration levels are shown in Figures 9 to 12. Additional analysis and data is required to evaluate if any significant difference is noted. Modifications to the computer program listed in Enclosure 2 are still required to vary the bin size and make the program more user friendly.

(1) MOMENT, CENTRAL MOMENT AND CUMULANT

1-1 MOMENT AND CHARACTERISTIC FUNCTION

For a single random variable (RV) x :

$p(x)$ = pdf (probability density function)

$Q(v)$ = Characteristic Function is = FT[$p(x)$]

$$= \int p(x) \exp(jxv) dx = E [\exp(jxv)]$$

$$M1=E[x]= \int x p(x) dx = (-j) \frac{\partial Q(v)}{\partial v} \bigg|_{v=0} = \text{Mean}$$

$$M2=E[x]^2= \int x^2 p(x) dx = (-j)^2 \frac{\partial^2 Q(v)}{\partial v^2} \bigg|_{v=0} = \text{Mean Square}$$

$M3= E[x]^3 \rightarrow$ Skewness \rightarrow Indication of Symmetric/nonsymmetric distribution

$M4= E[x]^4 \rightarrow$ Kurtosis \rightarrow Indication of Impulsive data

.
. .
. .
. .
. .
. .

. .

$$Mn=E[x]^n= \int x^n p(x) dx = (-j)^n \frac{\partial^n Q(v)}{\partial v^n} \bigg|_{v=0}$$

$E[\cdot]$: expect value operator

1-2 JOINT MOMENT and CENTRAL MOMENT

for a set of random variable x_1, x_2, \dots, x_n :

$p(x_1, x_2, \dots, x_n)$ = Joint probability Density Function

$Q(v_1, v_2, \dots, v_n)$ = Characteristic Function

= N-Dimensional FT{ $p(x_1, x_2, \dots, x_n)$ }

$$= \iiint \dots \int p(x_1, x_2, \dots, x_n) \exp(j \sum_{i=1}^n x_i v_i) dx_1 dx_2 \dots dx_n$$

$$= E [\exp(j \sum_{i=1}^n x_i v_i)]$$

--JOINT MOMENT:

$$M_{12} \dots n = E[x_1 x_2 \dots x_n] = (-j)^n \frac{\partial^n Q(v_1, v_2, \dots, v_n)}{\partial v_1 \partial v_2 \dots \partial v_n} \Big|_{v_1, v_2, \dots, v_n = 0}$$

$$= \iiint \dots \int (x_1 x_2 \dots x_n) p(x_1, x_2, \dots, x_n) dx_1 dx_2 \dots dx_n$$

--CENTRAL MOMENT:

. for 2 RV x_1 & x_2 :

C_{12} = Central Joint Moment (Covariance)

$$= E[(x_1 - M_1)(x_2 - M_2)] = M_{12} - M_1 M_2$$

--> if x_1 & x_2 are independent of each other, then C_{12} will be zero

$$\begin{aligned} \langle pf \rangle \quad C_{12} &= \iint (x_1 - M_1)(x_2 - M_2) p(x_1, x_2) dx_1 dx_2 \\ &= \int (x_1 - M_1) p(x_1) dx_1 \int (x_2 - M_2) p(x_2) dx_2 = 0 \end{aligned}$$

. for 3 RV x_1, x_2 & x_3 :

$$C_{123} = E[(x_1 - M_1)(x_2 - M_2)(x_3 - M_3)] = M_{123} - M_{12}M_3 - M_{13}M_2 - M_{23}M_1 + 2M_1M_2M_3$$

--> if (x_1, x_2, x_3) can be divided into two or three groups that are statistically independent of each other, then C_{123} will be zero.
 C_{123} will be non-zero only if (x_1, x_2, x_3) are correlated with one another

. For 4 RV x_1, x_2, x_3 & x_4 :

$$C_{1234} = E[(x_1 - M_1)(x_2 - M_2)(x_3 - M_3)(x_4 - M_4)]$$

$$= M_{1234} + (M_{34}M_{12} + M_{14}M_{23} + M_{24}M_{13} + M_{13}M_{24} + M_{23}M_{14} + M_{12}M_{34})$$

$$- (M_{134}M_2 + M_{234}M_1 + M_{124}M_3 + M_{123}M_4) - 3M_1M_2M_3M_4$$

--> $C_{1234} = 0$, ONLY if (x_1, x_2, x_3, x_4) can be divided into SOME CERTAIN subset that are statistically independent of each other.
 C_{1234} still be nonzero if (x_1, x_2, x_3, x_4) are correlated with one another. BUT C_{1234} will also be nonzero even though some subsets of RV are independent of other subsets.

FOR EXAMPLE, for 4 zero-mean RV (x_1, x_2, x_3, x_4) , if $(x_1$ cor $x_2)$ and $(x_3$ cor $x_4)$, but (x_1, x_2) independent of (x_3, x_4)

$$\text{---> } M_1 = M_2 = M_3 = M_4 = 0 \quad M_{12} \neq 0 \quad M_{34} \neq 0 \quad M_{1234} = M_{12}M_{34} \neq 0$$

$$C_{1234} = M_{1234} = M_{12}M_{34} \neq 0$$

. When C_{1234} is non-zero, it is possible that some subsets of the RV are still independent of other subsets of RV. (Not Desired)

. Need a statistics: ----> CUMULANT

{	zero:	As long as the RV's can be divided into two or more groups that are statistically independent of one another.
	nonzero:	All the RV's are correlated with one another.

1-3 CUMULANT

for a set of RV's x_1, x_2, \dots, x_n , with joint probability density function $p(x_1, x_2, \dots, x_n)$ and characteristic function $Q(v_1, v_2, \dots, v_n)$:
The joint cumulant $K_{12} \dots n$:

$$K_{12} \dots n = K[x_1 x_2 \dots x_n] = (-j)^n \frac{\partial^n \ln [Q(v_1, v_2, \dots, v_n)]}{\partial v_1 \partial v_2 \dots \partial v_n} \bigg|_{v_1, v_2, \dots, v_n = 0}$$

Relationship between Moment and Cumulant :

Note: $Q(v_1, v_2, \dots, v_n) \Big|_{v_1, v_2, \dots, v_n=0} = 1$

n=1

$$K_1 = (-j) \frac{\partial \ln [Q(v_1)]}{\partial v_1} \Big|_{v_1=0} = (-j) \frac{\partial Q(v_1)/\partial v_1}{Q(v_1)} \Big|_{v_1=0} = (-j) \frac{\partial Q(v_1)}{\partial v_1} \Big|_{v_1=0} = -M_1$$

n=2

$$K_{12} = (-j)^2 \frac{\partial^2 \ln [Q(v_1, v_2)]}{\partial v_1 \partial v_2} \Big|_{v_1, v_2=0} = (-j)^2 \frac{\partial}{\partial v_2} \left\{ \frac{\partial Q(v_1, v_2)/\partial v_1}{Q(v_1, v_2)} \right\} \Big|_{v_1, v_2=0}$$

$$= (-j)^2 \frac{[\partial^2 Q(v_1, v_2)/\partial v_1 \partial v_2] Q(v_1, v_2) - \partial Q(v_1, v_2)/\partial v_1 \partial Q(v_1, v_2)/\partial v_2}{Q(v_1, v_2)} \Big|_{v_1, v_2=0}$$

$$= M_{12} - M_1 M_2 = C_{12}$$

n=3:

$$K_{123} = M_{123} - M_{12}M_3 - M_{13}M_2 - M_{23}M_1 + 2M_1M_2M_3 = C_{123}$$

n=4:

$$K_{1234} = M_{1234} - (M_{12}M_{34} + M_{13}M_{24} + M_{14}M_{23} + M_{123}M_4 + M_{124}M_3 + M_{134}M_2 + M_{234}M_1) + 2(M_{12}M_{34} + M_{13}M_{24} + M_{14}M_{23} + M_{23}M_1M_4 + M_{24}M_1M_3 + M_{34}M_1M_2) - 6M_1M_2M_3M_4$$

$$= 2 * C_{1234} - M_{1234} + (M_{123}M_4 + M_{124}M_3 + M_{134}M_2 + M_{234}M_1) - (M_{12}M_{34} + M_{13}M_{24} + M_{14}M_{23})$$

PROPERTY OF CUMULANT:

[1] if RV x_1, x_2, \dots, x_n can be divided into two or more groups that are statistically independent of each other, then its $K_{12\dots n}$ will be zero. (Note: the central moment $C_{12\dots n}$ would not necessarily be zero)

<proof> if $(x_1, x_2, \dots, x_m, x_{m+1}, \dots, x_n)$ can be divided into two independent groups: (x_1, x_2, \dots, x_m) & (x_{m+1}, \dots, x_n)

then $p(x_1, x_2, \dots, x_n) = p_1(x_1, x_2, \dots, x_m) p_2(x_{m+1}, x_{m+2}, \dots, x_n)$

$$Q(v_1, v_2, \dots, v_n) = \int \left(\dots \int_{(n)} p(x_1, x_2, \dots, x_n) \exp(j \sum_{i=1}^n x_i v_i) dx_1 \dots dx_n \right.$$

$$= \int \left(\dots \int_{(m)} p_1(x_1, \dots, x_m) \exp(j \sum_{i=1}^m x_i v_i) dx_1 dx_2 \dots dx_m \right.$$

$$\left. \int \left(\dots \int_{(n-m)} p_2(x_{m+1}, \dots, x_n) \exp(j \sum_{i=m+1}^n x_i v_i) dx_{m+1} \dots dx_n \right) \right.$$

$$= Q_1(v_1, \dots, v_m) Q_2(v_{m+1}, \dots, v_n)$$

$$K_{12\dots n} = (-j)^n \frac{\partial^n \ln [Q(v_1, \dots, v_n)]}{\partial v_1 \partial v_2 \dots \partial v_n} \Big|_{v_1, \dots, v_n=0}$$

$$= (-j)^n \frac{\partial^n \ln [Q_1(v_1, \dots, v_m) Q_2(v_{m+1}, \dots, v_n)]}{\partial v_1 \partial v_2 \dots \partial v_n} \Big|_{v_1, \dots, v_n=0}$$

$$= (-j)^n \frac{\partial^n \{ \ln [Q_1(v_1, \dots, v_m)] + \ln [Q_2(v_{m+1}, \dots, v_n)] \}}{\partial v_1 \partial v_2 \dots \partial v_n} \Big|_{v_1, \dots, v_n=0}$$

$$= 0$$

$\begin{cases} K_{12\dots n} \neq 0 & \Rightarrow \text{all of RV's } (x_1, x_2, \dots, x_n) \text{ are correlated} \\ K_{12\dots n} = 0 & \Rightarrow \text{some sub-sets of RV's are independent of other subsets} \end{cases}$

[2] if $\underline{x} = (x_1, x_2, \dots, x_n)$ is joint Gaussian, then $K_{12\dots n} = 0$ for $n > 2$

<proof>

Gaussian Probability Density Function:

$$p(x_1, x_2, \dots, x_n) = \frac{\exp(-(\underline{x} - \underline{m}_x)^T \Lambda_x^{-1} (\underline{x} - \underline{m}_x)/2)}{(2\pi)^{N/2} |\Lambda_x|^{1/2}}$$

Gaussian Characteristic Function:

$$Q(v_1, v_2, \dots, v_n) = \exp\left(j \underline{v}^T \underline{m}_x - 0.5 \underline{v}^T \Lambda_x \underline{v}\right)$$

$\Rightarrow \ln [Q(v_1, v_2, \dots, v_n)] =$ Quadratic function of (v_1, v_2, \dots, v_n)

$$K_{12\dots n} = K[x_1 x_2 \dots x_n] = (-j)^n \frac{\partial^n \ln [Q(v_1, v_2, \dots, v_n)]}{\partial v_1 \partial v_2 \dots \partial v_n} \bigg|_{v_1, v_2, \dots, v_n = 0} = 0 \text{ for } n > 2$$

Note: This can also be proof by using the property of Gaussian RV:

if (x_1, x_2, \dots, x_n) be a set of Gaussian RV with C_{ij} being the covariance between x_i & x_j , then

$$\begin{cases} C_{12\dots n} = 0 & \text{if } n \text{ is odd} \\ C_{12\dots n} = \sum_{j_1 j_2} C_{j_1 j_2} C_{j_3 j_4} \dots C_{j_{n-1} j_n} & \text{if } n \text{ is even} \end{cases}$$

The summation is over all distinct pairs of subscripts (j_1, j_2, \dots, j_n) that are permutation of $(1, 2, \dots, n)$

Example: for $n=4$, $C_{1234} = C_{12} C_{34} + C_{13} C_{24} + C_{14} C_{23}$

[3] IN GENERAL, treat $K[]$ operator just as a symbol, which represents certain combination of $E[]$, rather than being an operator that can skip over an operator on the RV.

EXAMPLE: RV's (x, y, z) transform into new RV's (r, s) as:

$$r = a x ; s = b y z \quad (a, b = \text{constant})$$

$$\text{RIGHT: } K[rs] = E[rs] - E[r] E[s] = ab E[xyz] - ab E[x] E[y z]$$

$$\begin{aligned} \text{WRONG: } K[rs] &= K[(ax) (byz)] = ab K[xyz] \\ &= ab \{ E[xyz] - E[xy]E[z] - E[xz]E[y] - E[yz]E[x] + 2E[x]E[y]E[z] \} \end{aligned}$$

. If $L()$ represent a linear transformation operator which satisfy:

$$L_1(x_1) L_2(x_2) = L_1 L_2(x_1 x_2), \quad \text{then } K[L()] = L(K[])$$

$$\text{e.g. } L(x) = \text{Fourier Transform} = \int x(t) \exp(j \omega t) dt$$

$$\begin{aligned} L_1(x_1) L_2(x_2) &= \int x_1(t_1) \exp(j \omega_1 t_1) dt_1 \int x_2(t_2) \exp(j \omega_2 t_2) dt_2 \\ &= \iint x_1(t_1) x_2(t_2) \exp(j \omega_1 t_1) \exp(j \omega_2 t_2) dt_1 dt_2 = L_1 L_2(x_1 x_2) \end{aligned}$$

Example:

$$\begin{aligned} . K[L_1(x_1) L_2(x_2)] &= E[L_1(x_1) L_2(x_2)] - E[L_1(x_1)] E[L_2(x_2)] \\ &= E[L_1 L_2(x_1 x_2)] - L_1(E[x_1]) L_2(E[x_2]) \\ &= L_1 L_2(E[x_1 x_2]) - L_1 L_2(E[x_1] E[x_2]) \end{aligned}$$

$$\begin{aligned} . K[L_1(x_1) L_2(x_2)] &= K[L_1 L_2(x_1 x_2)] = L_1 L_2(K[x_1 x_2]) \\ &= L_1 L_2(E[x_1 x_2]) - L_1 L_2(E[x_1] E[x_2]) \end{aligned}$$

(2) HIGH ORDER SPECTRUM

2-1 CUMULANT FUNCTION (TIME DOMAIN)

For a random time series $x(t)$, the n -th order cumulant function:

$$K_n(t_1, t_2, \dots, t_n) = K[x(t_1) x(t_2) \dots x(t_n)]$$

if $x(t)$ is stationary, it only depends on the $n-1$ time lag variables:

time lag variables: $T_i = t_i - t_n$

$$\begin{aligned} K_n(t_1, t_2, \dots, t_n) &= K[x(t_n) x(t_n + T_1) x(t_n + T_2) \dots x(t_n + T_{n-1})] \\ &= K_n(T_1, T_2, \dots, T_{n-1}) \end{aligned}$$

SPECIAL CASE WHEN $n=2$:

$$K_2(T) = K[x(t) x(t+T)] = R_{xx}(T) = \text{auto-correlation function (a.c.f)}$$

2-2 CUMULANT SPECTRUM (FREQUENCY DOMAIN):

$$F_n(\omega_1, \omega_2, \dots, \omega_{n-1}) = \text{N-th ORDER CUMULANT SPECTRUM} = \text{FT} \{ K_n(T_1, T_2, \dots, T_{n-1}) \}$$

(n-1 D)

$$F_n(\omega_1, \omega_2, \dots, \omega_{n-1}) = \int \dots \int_{n-1} K_n(T_1, T_2, \dots, T_{n-1}) \exp(j \sum_{i=1}^{n-1} \omega_i T_i) dT_1 dT_2 \dots dT_{n-1}$$

--> This involves the estimation of cumulant function $K_n(T_1, T_2, \dots, T_{n-1})$, as well as multi-dimensional Fourier Transform

--> Wish to find a direct relationship between cumulant spectrum and the FT of $x(t)$.

Relationship Between $F_n(w_1, w_2, \dots, w_{n-1})$ and $X(w)$:

.....

. If $x(t)$ be real and stationary, $X(w) = FT[x(t)] = \int x(t) \exp(j wt) dt$
then $X(w)$ will be zero-mean at non-zero frequency, i.e.

$$E[X(w)] = E[x(t)] \delta(w) \quad (E[X(0)] = E[x(t)])$$

<proof> $E[X(w)] = E\left[\int_{-\infty}^{\infty} x(t) \exp(jwt) dt\right] = \int_{-\infty}^{\infty} E[x(t)] \exp(jwt) dt$
 $= E[x(t)] \delta(w)$ #

$$\bullet \frac{K[X(w1) X(w2) \dots X(w_n)]}{=K[\int x(t1)\exp(j w1t1)dt1 \int x(t2)\exp(j w2t2)dt2 \dots \int x(tn)\exp(j wntn)dt_n]}$$

$$=K[\int \int \dots \int_{(n)} x(t_1)x(t_2) \dots x(t_n) \exp(j \sum_{i=1}^n w_i t_i) dt_1 dt_2 \dots dt_n]$$

$$= \int \dots \int_{(n)} K[x(t_1) \ x(t_2) \ \dots x(t_n)] \exp(j \sum_{i=1}^n w_i t_i) dt_1 dt_2 \dots dt_n$$

$$= \int \dots \int_{(n)} K_n(t_1, t_2, \dots, t_n) \exp(j \sum_{i=1}^n w_i t_i) dt_1 dt_2 \dots dt_n$$

change of variable: $T_i = t_i - t_n$ for $i = 1, 2, \dots, n-1$

$$\begin{array}{ll} t_i & \text{---> } T_i + t_n \\ dt_i & \text{---> } dT_i \\ K_n(t_1, t_2, \dots, t_n) & \text{---> } K_n(T_1, T_2, \dots, T_{n-1}) \quad (\text{for stationary}) \end{array}$$

$$= \int \cdots \int_{(n)} K_n(T_1, T_2, \dots, T_{n-1}) \exp[j \sum_{i=1}^n w_i (T_i + t_n)] dT_1 dT_2 \dots dT_{n-1} dt_n$$

$$= \int \dots \int_{(n-1)} K_n(T_1, T_2 \dots T_{n-1}) \exp(j \sum_{i=1}^{n-1} w_i T_i) dT_1 dT_2 \dots dT_{n-1} \int \exp(j t_n \sum_{i=1}^n w_i) dt_n$$

$$= \{ \text{n-1 dimensional FT of } K_n(T_1, T_2, \dots, T_{n-1}) \} \delta \left(\sum_{i=1}^n w_i \right)$$

$$= \{ F_n(w_1, w_2, \dots, w_{n-1}) \} \delta(w_1 + w_2 + \dots + w_n)$$

$$|K[X(w_1) X(w_2) \dots X(w_n)] = \{F_n(w_1, w_2, \dots, w_{n-1})\} \delta(w_1 + w_2 + \dots + w_n) \quad (*)$$

where, delta function: $\delta(u) = \exp(j tu) dt \begin{cases} = 1 & \text{for } u = 0 \\ = 0 & \text{for } u \neq 0 \end{cases}$

Two Important Statistical Concept From Equation (*):

[1] $K[X(w_1) X(w_2) \dots X(w_n)]$ will be non-zero, only $w_1 + w_2 + \dots + w_n = 0$

Because only in this case, the delta function becomes non-zero.

$K[X(w_1) X(w_2) \dots X(w_n)] = 0$ for any other arbitrary freq combination

EXAMPLE:

(1) observe $\begin{cases} 50\text{Hz signal in channel-x} \\ 50\text{Hz signal in channel-y} \end{cases}$

can identify whether the 50Hz signal in channel x & y are correlated by examining the linear cross-spectrum (2nd order cumulant spectrum):

$$K[X(50\text{Hz}) Y(-50\text{Hz})] = F_2(50\text{Hz}) = S_{xy}(50\text{Hz}) \implies \text{freq sum} = \text{zero}$$

(2) observe $\begin{cases} 50\text{Hz signal in channel-x} \\ 80\text{Hz signal in channel-y} \end{cases}$

can not simply examine the 2-nd order cumulant spectrum at these two frequencies as:

$$K[X(50\text{ Hz}) Y(+ - 80\text{Hz})] \text{ is always zero (sum freq is not zero)}$$

[2] Sum frequency $(w_1 + w_2 + \dots + w_n) = 0 \implies w_n = -(w_1 + w_2 + \dots + w_{n-1})$

$$\implies F_n(w_1, w_2, \dots, w_{n-1}) = K[X(w_1) X(w_2) \dots X(w_{n-1}) X(-w_1 - w_2 - \dots - w_{n-1})]$$

$$F_n(w_1, w_2, \dots, w_{n-1}) = K[X(w_1) X(w_2) \dots X(w_{n-1}) X(w_1 + w_2 + \dots + w_{n-1})] \quad (**) \quad \left| \begin{array}{c} * \\ \hline \end{array} \right|$$

. This equation allows us to evaluate cumulant spectrum directly from the FT of $x(t)$ without having to evaluate cumulant function and performing multi-dimensional FT.

. Recall the property of cumulant average:
If RV x_1, x_2, \dots, x_n can be divided into two or more groups which are statistically independent of each other, then $K[x_1 x_2 \dots x_n] = 0$

Equation (**) imply that:

If the waves at frequencies w_1, w_2, \dots, w_n can be divided into two or more groups which are independent of each other, then $F_n(w_1, \dots, w_{n-1}) = 0$

If the waves at these different frequencies are nonlinearly correlated with each other, then $F_n(w_1, w_2, \dots, w_{n-1}) \neq 0$

2-3 LINEAR SPECTRUM (SPECIAL CASES FOR n=2)

- Auto-correlation and auto-spectrum of $x(t)$:

$$\begin{cases} K_{2xx}(T) = K [x(t) x(t+T)] = R_{xx}(T) = \text{a.c.f.} \\ F_{2xx}(w) = \int_{-\infty}^{\infty} K_{2xx}(T) \exp(j w T) dT = \int_{-\infty}^{\infty} R_{xx}(T) \exp(i w T) dT = S_{xx}(w) = \text{PSD} \\ F_{2xx}(w) = K [X(w) X(w)] = E [X(w) X(w)] = E [|X(w)|^2] = S_{xx}(w) = \text{PSD} \end{cases}$$

- Cross-Correlation, Cross-Spectrum, Cross-Coherence between $x(t)$ & $y(t)$

$$\begin{cases} K_{2xy}(T) = K [x(t) y(t+T)] = R_{xy}(T) = \text{c.c.f.} \\ F_{2xy}(w) = \int_{-\infty}^{\infty} K_{2xy}(T) \exp(j w T) dT = \int_{-\infty}^{\infty} R_{xy}(T) \exp(i w T) dT = S_{xy}(w) = \text{CSD} \\ F_{2xy}(w) = K [X(w) Y(w)] = E [X(w) Y(w)] = S_{xy}(w) = \text{CSD} \end{cases}$$

$$r_{xy}^2(w) = \frac{|S_{xy}(w)|^2}{[S_{xx}(w) S_{yy}(w)]} = \text{linear cross-coherence function}$$

Discrete form:

$$r_{xy}^2(w) = \frac{[\sum_i X_i(w) Y_i(w)]^2}{[\sum_i |X_i(w)|^2] [\sum_i |Y_i(w)|^2]} = \text{linear cross-coherence function}$$

- Coherence is bounded by one

< proof > by using Cauchy's Inequality:

(i) for any random variables x, y , real or complex

$$|E[xy]|^2 \leq E[|x|^2] E[|y|^2]$$

(ii) for any sequences x_i, y_i , real or complex

$$| \sum_i x_i y_i |^2 \leq \sum_i |x_i|^2 \sum_i |y_i|^2$$

- System Identification for Linear Time Invariant (LTI) system:

$$x(t) \xrightarrow{\quad} | \overline{h(t), H(w)} | \xrightarrow{\quad} y(t)$$

$$y(t) = x(t) * h(t) = \int_{-\infty}^{\infty} x(t-a) h(a) da \Rightarrow Y(w) = X(w) H(w)$$

$$S_{xy}(w) = E [X(w) Y(-w)] = E [X(w) X(-w) H(-w)] = S_{xx}(w) H(w)$$

$$\Rightarrow H(w) = \frac{S_{xy}(w)}{S_{xx}(w)}$$

2-4 BISPECTRUM (WHEN $n=3$)

Auto-Bispectrum

. Auto-bicorrelation, auto-bispectrum & auto-bicoherence of $x(t)$:

$$\begin{cases} K_{3xxx}(T_1, T_2) = K [x(t) x(t+T_1) x(t+T_2)] = R_{xxx}(T_1, T_2) = \text{a.b.c.f} \\ F_{3xxx}(\omega_1, \omega_2) = \int K_{3xxx}(T_1, T_2) \exp[j(\omega_1 T_1 + \omega_2 T_2)] dT_1 dT_2 = B_{xxx}(\omega_1, \omega_2) \\ F_{3xxx}(\omega_1, \omega_2) = K [X(\omega_1) X(\omega_2) X(\omega_1 + \omega_2)] = B_{xxx}(\omega_1, \omega_2) = \text{ABS} \end{cases}$$

$$b_{xxx}^2(\omega_1, \omega_2) = \frac{1 B_{xxx}(\omega_1, \omega_2) 1}{E[1 X(\omega_1) X(\omega_2) 1] S_{xx}(\omega_1 + \omega_2)} = \text{Auto-Bi-coherence (ABC)}$$

Discrete form:

$$b_{xxx}^2(\omega_1, \omega_2) = \frac{| X_i(\omega_1) X_i(\omega_2) X_i(\omega_1 + \omega_2) |^2}{[| X_i(\omega_1) X_i(\omega_2) |] [| X_i(\omega_1 + \omega_2) |]}$$

Region of ABS:

Maximum frequency = Nyquist Frequency ω_q = Sampling Frequency/2

Auto-Bispectrum will only be defined over a hexagon:

$$-\omega_q < \omega_1, \omega_2 < \omega_q \quad \text{and} \quad -\omega_q < \omega_1 + \omega_2 < \omega_q$$

SYMMETRIC PROPERTY:

$B(w_1, w_2) = K[X(w_1) X(w_2) X(-w_1-w_2)] \implies 6 \text{ different permutation:}$

$$(w_1, w_2; -w_1-w_2) \quad (w_2, -w_1-w_2; w_1) \quad (-w_1-w_2, w_1; w_2)$$

$$(w_2, w_1; -w_1-w_2) \quad (w_1, -w_1-w_2; w_2) \quad (-w_1-w_2, w_2; w_1)$$

$$B(w_1, w_2) = K[X(w_1)X(w_2)X(-w_1-w_2)] = K[X(-w_1)X(-w_2)X(w_1+w_2)]$$

$\implies 6 \text{ more permutation:}$

$$(-w_1, -w_2; w_1+w_2) \quad (-w_2, w_1+w_2; -w_1) \quad (w_1+w_2, -w_1; -w_2)$$

$$(-w_2, -w_1; w_1+w_2) \quad (-w_1, w_1+w_2; -w_2) \quad (w_1+w_2, -w_2; -w_1)$$

$$\implies B_{xxx}(w_1, w_2) = B_{xxx}(w_2, -w_1-w_2) = B_{xxx}(-w_1-w_2, w_1)$$

$$= B_{xxx}(w_2, w_1) = B_{xxx}(w_1, -w_1-w_2) = B_{xxx}(-w_1-w_2, w_2)$$

$$= B_{xxx}(-w_1, -w_2) = B_{xxx}(-w_2, w_1+w_2) = B_{xxx}(w_1+w_2, -w_1)$$

$$= B_{xxx}(-w_2, -w_1) = B_{xxx}(-w_1, w_1+w_2) = B_{xxx}(w_1+w_2, -w_2)$$

$$B_{xxx}(w_1, w_2) = B_{xxx}(w_2, w_1) \quad / \quad MP = (w_1+w_2/2, w_2+w_1/2) \implies \text{SYM wrt } 45^\circ \text{ line}$$

$$B_{xxx}(w_1, w_2) = B_{xxx}(-w_2, -w_1) \quad / \quad MP = (w_1-w_2/2, w_2-w_1/2) \implies \text{Conj SYM WRT } -45^\circ \text{ line}$$

$$B_{xxx}(w_1, w_2) = B_{xxx}(w_1, -w_1-w_2) \quad / \quad MP = (w_1, -w_1/2) \implies \text{Sym vertically WRT Middle Line: } w_1 = -2w_2$$

Cross-Bispectrum

. Cross-Bicorrelation, Cross-Bispectrum, Cross-Bicoherence between x & y

$$\begin{cases} K_{3xy}(T_1, T_2) = K [x(t) x(t+T_1) y(t+T_2)] = R_{xy}(T_1, T_2) = \text{c.b.c.f} \\ F_{3xy}(w_1, w_2) = K_{3xy}(T_1, T_2) \exp[j(w_1 T_1 + w_2 T_2)] \int dT_1 dT_2 = B_{xy}(w_1, w_2) \\ F_{3xy}(w_1, w_2) = K [X(w_1) X(w_2) Y(w_1+w_2)] = B_{xy}(w_1, w_2) = \text{CBS} \end{cases}$$

$$b_{xy}^2(w_1, w_2) = \frac{|B_{xy}(w_1, w_2)|^2}{E[|X(w_1) X(w_2)|^2] S_{yy}(w_1+w_2)} = \text{Cross-Bi-coherence (CBC)}$$

Discrete form:

$$b_{xy}^2(w_1, w_2) = \frac{|X_i(w_1) X_i(w_2) Y_i(w_1+w_2)|^2}{[|X_i(w_1) X_i(w_2)|^2] [|Y_i(w_1+w_2)|^2]}$$

Region of CBS: Same Hexagon = $-W_q < w_1, w_2 < W_q$ & $-W_q < w_1+w_2 < W_q$

Symmetric Property:

$$\begin{aligned} B_{xy}(w_1, w_2) &= K[X(w_1) X(w_2) Y(-w_1-w_2)] = K[X(w_2) X(w_1) Y(-w_1-w_2)] = B_{xy}(w_2, w_1) \\ B_{xy}(-w_1, -w_2) &= K[X(-w_1) X(-w_2) Y(w_1+w_2)] = K[X(-w_2) X(-w_1) Y(w_1+w_2)] = B_{xy}(-w_2, -w_1) \end{aligned}$$

$$\implies B_{xy}(w_1, w_2) = B_{xy}(w_2, w_1) = B_{xy}(-w_1, -w_2) = B_{xy}(-w_2, -w_1)$$

$$B_{xy}(w_1, w_2) = B_{xy}(w_2, w_1) \quad / \quad \text{MP} = (w_1+w_2/2, w_2+w_1/2) \implies \text{SYM WRT } 45 \text{ line}$$

$$B_{xy}(w_1, w_2) = B_{xy}(-w_2, -w_1) \quad / \quad \text{MP} = (w_1-w_2/2, w_2-w_1/2) \implies \text{Conj SYM WRT } -45 \text{ line}$$

2-5 System Identification for Quadratic Time Invariant (QTI) system:

INPUT/OUTPUT RELATIONSHIP:

Let $x(t)$ be zero-mean, and $y(t)$ be the output of a quadratic system:

$$x(t) \text{ ----> } \boxed{g(t_1, t_2), G(w_1, w_2)} \text{ -----> } y(t)$$

$G(w_1, w_2)$ = Quadratic Transfer Function (QTF) = FT{ $g(t_1, t_2)$ }

$$G(w_1, w_2) = \iint g(t_1, t_2) \exp[j(w_1 t_1 + w_2 t_2)] dt_1 dt_2$$

Note: $G(w_1, w_2) = G^*(w_2, w_1)$

$G(w_1, w_2) = G(-w_1, -w_2)$

$Y(0) = \int G(a, -a) X(a) X(-a) da$

$$\begin{aligned} \Rightarrow E[y(t)] &= E[Y(0)] = \int G(a, -a) E[X(a)X(-a)] da \\ &= \int G(a, -a) S_{xx}(a) da \end{aligned}$$

$$y(t) = x(t) ** g(t_1, t_2) = \iint x(t-a)x(t-b) g(a, b) da db$$

$$= \iiint g(a, b) \int X(w_1) \exp[-j(t-a)w_1] dw_1 \int X(w_2) \exp[-j(t-b)w_2] dw_2 da db$$

$$= \iiint \left\{ \iint g(a, b) \exp[j(a w_1 + b w_2)] da db \right\} X(w_1) X(w_2) \exp[-j(w_1 + w_2)t] dw_1 dw_2$$

$$= \iint G(w_1, w_2) X(w_1) X(w_2) \exp[-j(w_1 + w_2)t] dw_1 dw_2$$

$$Y(w) = \iint G(w_1, w_2) X(w_1) X(w_2) \text{FT}\{ \exp[-j(w_1 + w_2)t] \} dw_1 dw_2$$

$$= \iint G(w_1, w_2) X(w_1) X(w_2) \delta(w - w_1 - w_2) dw_1 dw_2$$

$$= \int G(w_1, w-w_1) X(w_1) X(w-w_1) dw_1$$

$$\Rightarrow \boxed{Y(w) = \int G(a, w-a) X(a) X(w-a) da}$$

QTF IDENTIFICATION:

$$\begin{aligned}
 B_{xy}(w_1, w_2) &= K[X(w_1) X(w_2) Y(-w_1-w_2)] \\
 &= E[X(w_1) X(w_2) Y(-w_1-w_2)] - E[X(w_1) X(w_2)] E[Y(-w_1-w_2)] \\
 &\quad - E[X(w_1) Y(-w_1-w_2)] E[X(w_2)] - E[X(w_2) Y(-w_1-w_2)] E[X(w_1)] \\
 &= E[X(w_1) X(w_2) \int G(a, -w_1-w_2-a) X(a) X(-w_1-w_2-a) da] \\
 &\quad - E[X(w_1) X(w_2)] E[Y(-w_1-w_2)] \\
 &= \int G(a, -w_1-w_2-a) E[X(w_1) X(w_2) X(a) X(-w_1-w_2-a)] da \\
 &\quad - E[X(w_1) X(w_2)] E[Y(-w_1-w_2)] \\
 &= \int G(a, -w_1-w_2-a) \{ E[X(w_1) X(a)] E[X(w_2) X(-w_1-w_2-a)] \\
 &\quad + E[X(a) X(w_2)] E[X(w_1) X(-w_1-w_2-a)] \\
 &\quad + E[X(w_1) X(w_2)] E[X(a) X(-w_1-w_2-a)] \} da \\
 &\quad - E[X(w_1) X(w_2)] E[Y(-w_1-w_2)] \\
 &= \int G(a, -w_1-w_2-a) \{ E[X(w_1) X(a)] E[X(w_2) X(-w_1-w_2-a)] \delta(w_1+a) \\
 &\quad + E[X(a) X(w_2)] E[X(w_1) X(-w_1-w_2-a)] \delta(w_2+a) \\
 &\quad + E[X(w_1) X(w_2)] E[X(a) X(-w_1-w_2-a)] \delta(w_1+w_2) \} da \\
 &\quad - E[X(w_1) X(w_2)] E[Y(-w_1-w_2)] \delta(w_1+w_2) \\
 &= G(-w_1, -w_2) S_{xx}(w_1) S_{xx}(w_2) + G(-w_2, -w_1) S_{xx}(w_2) S_{xx}(w_1) \\
 &\quad + S_{xx}(w_1) \int G(a, -a) S_{xx}(a) da - S_{xx}(w_1) E[y(t)] \\
 &= 2 S_{xx}(w_1) S_{xx}(w_2) G(w_1, w_2) + S_{xx}(w_1) \{ \int G(a, -a) S_{xx}(a) da - E[y(t)] \} \\
 &= 2 S_{xx}(w_1) S_{xx}(w_2) G(w_1, w_2)
 \end{aligned}$$

$$\Rightarrow \boxed{ G(w_1, w_2) = \frac{B_{xy}(w_1, w_2)}{2 S_{xx}(w_1) S_{xx}(w_2)} }$$

EXAMPLE:

If $x(t)$ is zero-mean Gaussian White Noise (GWN), and $S_{xx}(w) = 1$

$$x(t) \text{ ----> } \boxed{h(t), H(w)} \text{ ----> } \boxed{\text{SQUARER}} \text{ ----> } y(t) = z^2(t)$$

I/O relationship $\Rightarrow Y(w) = \int G(a, w-a) X(a) X(w-a) da$

$y(t) = z(t) z(t) \Rightarrow Y(w) = \int Z(a) Z(w-a) da = \int H(a) H(w-a) X(a) X(w-a) da$

$\Rightarrow G(w_1, w_2) = H(w_1) H(w_2) = B_{xxy}(w_1, w_2)/2$

$w_1 = w_2 = w \Rightarrow H(w) = B_{xxy}(w, w)/2 \Rightarrow H(w) = \{ 0.5 B_{xxy}(w, w) \}^{0.5}$

SIMULATION EXAMPLE FOR AUTO-BICOHERENCE

$$\begin{cases} X_1(t) = \cos(W_1 t + \phi_1) + \cos(W_2 t + \phi_2) + \cos[(W_1 + W_2)t + (\phi_1 + \phi_2)] + N_1(t) \\ X_2(t) = \cos(W_1 t + \phi_1) + \cos(W_2 t + \phi_2) + \cos[(W_1 + W_2)t + \phi_3] + N_2(t) \\ X_3(t) = \cos(W_1 t + \phi_1) + \cos(W_2 t + \phi_2) + 0.5 \cos[(W_1 + W_2)t + (\phi_1 + \phi_2)] + \\ \quad 0.5 \cos[(W_1 + W_2)t + \phi_3] + N_3(t) \end{cases}$$

Where: $\begin{cases} \phi_1, \phi_2, \phi_3 \text{ are random phase} \end{cases}$

$\begin{cases} N_1, N_2, N_3 \text{ are independent GWN} \end{cases}$

$\begin{cases} X_1(t) = (W_1, W_2, W_3) \text{ are perfectly correlated} \end{cases}$

FRF 26 ME-3

PDP RAD 135-2

FIGURE 50. ISOPLOT OF PREBURNER PUMP RADIAL
 (135-2) ACCEL. FROM TEST FRF-26 ON ME-3

(1) SIDE-BAND PSD STRUCTURE DUE TO MODULATION:

Consider a vibration signal due to periodic impact on a structure with resonant freq ω_c

e.g. cage frequency component periodically excite a structure mode at its natural frequency (or a sensor's natural frequency)

Time Domain model: $x(t) = e(t) \cos[\omega_c t + p(t)]$

$\left\{ \begin{array}{l} e(t) = \text{envelope} = \text{periodic impact signal with dominant frequency } \omega_e \\ \cos[\omega_c t + p(t)] = \text{carrier} = \text{structural response at natural frequency } \omega_c \end{array} \right.$

Frequency Domain: \implies Side-Band Structure ($\omega_c - \omega_e$, ω_c , $\omega_c + \omega_e$)

(2) Envelope Detection :

$$\begin{cases} \text{measured signal: } x(t) = e(t) \cos[W_c t + p(t)] \\ 90 \text{ phase shift: } y(t) = e(t) \sin[W_c t + p(t)] \end{cases} \implies \text{envelope } e(t) = \sqrt{x(t)^2 + y(t)^2}$$

. Hilbert Transform:

$$y(t) = \text{HT} [x(t)] = x(t) * h(t) \quad \iff \quad Y(w) = X(w) H(w)$$

$$H(w) = 90 \text{ phase shifter} = -j \operatorname{sgn}(w) = \begin{cases} -j & = \exp(-j \pi/2) \quad \text{for } w > 0 \\ +j & = \exp(+j \pi/2) \quad \text{for } w < 0 \end{cases}$$

----> PSD at Output of Squarer for Both $x(t)$ and $y(t)$:

--> PSD of Envelope:

Note: Harmonics Might Show Up Due to The SQUARE and SQUARE ROOT Operation in The Envelope Detection, and Is Dependent On the MODULATION INDEX

TRISPECTRAL ANALYSIS

(3) AUTO/CROSS TRISPECTRUM & TRICHERENCE

Auto-tricorrelation, auto-trispectrum & auto-tricoherence of $x(t)$:

$$K4xxxx(T1, T2, T3) = K[x(t)x(t+T1)x(t+T2)x(t+T3)] = Rxxxx(T1, T2, T3) = \text{a.t.c.}$$

$$F4xxxx(w1, w2, w3) = \iiint K4xxxx(T1, T2, T3) \exp[j(w1T1 + w2T2 + w3T3)] dT1 dT2 dT3 \\ = Txxxx(w1, w2, w3) = \text{Auto-Tri-Spectrum (ATS)}$$

$$F4xxxx(w1, w2, w3) = K[X(w1)X(w2)X(w3)X(w1+w2+w3)] = Txxxx(w1, w2, w3) = \text{ATS}$$

$$= E[X(w1)X(w2)X(w3)X(w1+w2+w3)] - E[X(w1)X(w2)] E[X(w3)X(w1+w2+w3)] \\ - E[X(w1)X(w3)] E[X(w2)X(w1+w2+w3)] - E[X(w2)X(w3)] E[X(w1)X(w1+w2+w3)]$$

$$t_{xxxx}(w1, w2, w3) = \frac{1}{E[1 X(w1)X(w2)X(w3) 1]} \frac{Txxxx(w1, w2, w3)}{E[1 X(w1+w2+w3) 1]} = (\text{ATC})$$

Discrete Form:

$$t_{xxxx}(w1, w2, w3) = \frac{1}{[\sum 1 X_i(w1)X_i(w2)X_i(w3) 1^2]} \frac{Txxxx(w1, w2, w3)}{[\sum 1 X_i(w1+w2+w3) 1^2]}$$

Where:

$$Txxxx(w1, w2, w3) = | \sum X_i(w1) X_i(w2) X_i(w3) X_i(w1+w2+w3) | \\ - | \sum X_i(w1) X_i(w2) | | \sum X_i(w3) X_i(w1+w2+w3) | \\ - | \sum X_i(w1) X_i(w3) | | \sum X_i(w2) X_i(w1+w2+w3) | \\ - | \sum X_i(w2) X_i(w3) | | \sum X_i(w1) X_i(w1+w2+w3) |$$

$X_i(w)$ = Fourier Transform of $x(t)$ at i -th ensemble Average Block

(4) Tri-Spectral Analysis for Side-Band Identification:

$$x(t) = [A + e(t)] \cos[W_c t + P_c(t)]$$

Where: $e(t) = \text{envelope} = \cos[W_e t + P_e(t)]$

$$\text{-----} \rightarrow \begin{cases} \text{left side-band} & \cos[\{W_c - W_e\} t + \{P_c(t) - P_e(t)\}] \\ \text{center} & \cos[W_c t + P_c(t)] \\ \text{right side+band} & \cos[\{W_c + W_e\} t + \{P_c(t) + P_e(t)\}] \end{cases}$$

OBSERVATION: NOT ONLY the frequencies become sum and difference,
BUT ALSO their phase drifting become sum and difference.

This Phase correlation can be identified by using the

Tri-Coherence:

$$T_{xxxx}(\begin{matrix} W_1 = W_c - W_e, \\ \text{LEFT} \end{matrix}, \begin{matrix} W_2 = -W_c, \\ \text{-CENTER} \end{matrix}, W_3 = W) \quad \text{NOTE: SUM FREQ} = W - W_e$$

$$\begin{cases} \text{MODULATION SIDE-BAND} \text{ ---} \rightarrow T_{xxxx}(\text{LEFT}, \text{-CENTER}, W_3 = \text{RIGHT}) = 1 \\ \text{INDEPENDENT SIDE-BAND} \text{ ---} \rightarrow T_{xxxx}(\text{LEFT}, \text{-CENTER}, W_3 = \text{RIGHT}) = 0 \end{cases}$$

$$T_{xxxx}(\text{LEFT}, \text{-CENTER}, W_3 = \text{RIGHT})$$

= Ensemble Average of { Phase(LEFT) + Phase(RIGHT) - 2 Phase(CENTER) }

$$= \begin{cases} \text{constant compound phase for modulation side-band} \\ \text{random compound phase for independent side-band} \end{cases} = \begin{cases} 1 \\ 0 \end{cases}$$

(5) SIMULATION: SINGLE SIDE BAND, AM, FM, PPM, PSK, QAM, etc.

[1] Modulation Side-Band :

$$x(t) = \underbrace{\{ 5 + \cos[W_e t + p_1(t)] \}}_{\text{Envelope}} \underbrace{\cos[W_c t + p_2(t)]}_{\text{Carrier}} + N(t)$$

PSD:

$$\left\{ \begin{array}{l} \text{Envelope at } W_e = 200 \text{ Hz} \\ \text{Carrier at } W_c = 3000 \text{ Hz} \end{array} \right. \quad \text{--->} \quad \left\{ \begin{array}{l} \text{Left Side-Band } W_c - W_e = 2800 \text{ Hz} \\ \text{Center Frequency } W_c = 3000 \text{ Hz} \\ \text{Right Side-Band } W_c + W_e = 3200 \text{ Hz} \end{array} \right.$$

[2] Independent Side-Band :

$$y(t) = \cos[(W_c - W_e)t + p_3(t)] + 10 \cos[W_c t + p_4(t)] \\ + \cos[(W_c + W_e)t + p_5(t)] + N(t)$$

PSD:

$$\left\{ \begin{array}{l} \text{Left Side-Band } W_c - W_e = 2800 \text{ Hz} \\ \text{Center Frequency } W_c = 3000 \text{ Hz} \\ \text{Right Side-Band } W_c + W_e = 3200 \text{ Hz} \end{array} \right.$$

Where:

$$\left\{ \begin{array}{l} p_1(t), p_2(t), p_3(t), p_4(t), p_5(t) = \text{Independent Phase Drifting} \\ N(t) = \text{Gaussian White Noise} \end{array} \right.$$

Figure 8. Isoplot of Measurement from Test 901-471

HYPER-COHERENCE AND HYPER-COHERENCE FILTERING

(1) PERIODIC SIGNAL

. Periodic Signal With $\begin{cases} T = \text{Period} \\ f_1 = 1/T = \text{Fundamental Frequency (} \omega_1 = 2\pi f_1 \text{)} \end{cases}$

$\begin{cases} \text{Time Domain:} & x(t) = x(t + T) \\ \text{Frequency Domain:} & X(\omega) = X(\omega) \exp(j\omega T) \end{cases}$

If $X(\omega) \neq 0$, then $\exp(j\omega T) = 1 \implies \omega T = 2\pi f/f_1 = k 2\pi \implies f = k f_1$

Therefore, for a periodic signal, its Fourier Transform $X(\omega)$ can be non-zero only at the integer-multiple of the fundamental frequency:

$(f_1, 2*f_1, 3*f_1, \dots, k*f_1, \dots)$

Any other non-zero $X(\omega)$ at non-integer-multiple frequency will violate the periodicity assumption.

\implies time domain model: $x(t) = \sum_{n=1}^{\infty} A_n \cos(n \omega_1 t + \phi_n)$

. In order to maintain a fixed pattern of waveform, the phase between the fundamental frequency component and all of its harmonics must maintain some constant phase relationship.

\implies HOW to identify and establish such phase relationship between different frequency components ????

(2) HYPER-COHERENCE

$$\left\{ \begin{array}{l} B_{xxxx}(w_1, w_1) = K[X(w_1) X(w_1) X(2 W_1)] \\ T_{xxxx}(w_1, w_1, w_1) = K[X(w_1) X(w_1) X(w_1) X(3 W_1)] \\ Q_{xxxxx}(w_1, w_1, w_1, w_1) = K[X(w_1) X(w_1) X(w_1) X(W_1) X(4 w_1)] \\ \vdots \\ F_n(w_1, w_1, w_1, \dots) = K[X(w_1) X(w_1) \dots X(n w_1)] \end{array} \right.$$

Hyper-Spectrum:

$$HS(W_n; W_1) = K [X^n(W_1) X^{*}(n W_1)] = E [X^n(W_1) X^{*}(n W_1)]$$

Hyper-Coherence:

$$HC(W_n; W_1) = \frac{| HS(W_n; W_1) |^2}{E[| X(W_1) |^{2n}] E[| X(n W_1) |^2]}$$

. PHASE OF HYPER-SPECTRUM:

$$\begin{aligned} HS(W_n; W_1) &= E [X^n(W_1) X^{*}(n W_1)] \quad \text{Compound Phase } Q(W_n; W_1) \\ &= E [|X(W_1) X(n W_1)| e^{j \{ n P(W_1) - P(W_n) \}}] \end{aligned}$$

Original model:

$$x(t) = \sum_{n=1}^{\infty} A_n \cos[W_n t + P(W_n)] \quad \text{where } W_n = n * W_1$$

If we take measurement at any arbitrary time t_0 :

$$\left\{ \begin{array}{l} y(t) = x(t-t_0) = \sum A_n \cos[W_n (t-t_0) + P(W_n)] \\ \quad = \sum A_n \cos[W_n t + P(W_n) - W_n t_0] \\ Y(W) \Rightarrow \text{the observed Phase at } W_n = P'(W_n) = P(W_n) - W_n t_0, \text{ which} \\ \text{depends on the starting time of measurement } t_0, \text{ BUT the compound phase} \\ Q'(W_n; W_1) = n P'(W_1) - P'(W_n) = n [P(W_1) - W_1 t_0] - [P(W_n) - W_n t_0] \\ \quad = n P(W_1) - P(W_n) = \text{independent of } t_0 \end{array} \right.$$

[1] This compound phase $Q(W_n; W_1) = n P(W_1) - P(W_n)$, provides an inherent phase relationship between the fundamental component and its n-th order harmonic. It will remain a constant phase for a fixed pattern of periodic waveform.

EX: We observe 100 Hz and 400 Hz spectral component in a signal.

If 400 Hz is 4th Harmonic of 100 Hz: $Q(W_n; W_1) = \text{constant phase}$

==> Hyper-Coherence $HC(4N, N) = 1$

If 400 Hz is from other independent source: $Q(W_n; W_1) = \text{random phase}$

==> Hyper-Coherence $HC(4N, N) = 0$

====> Hyper-Coherence can be used to identify whether an apparent harmonic of some reference component is truly a harmonic of it or not

[2] If the periodic signal is corrupted by noise, then this inherent phase relationship can provide a way to perform waveform enhancement through ensemble average of the compound phase.

====> Hyper-Coherence Filtering:

- Phase Information Recovery

At the n-th harmonic of the i-th ensemble average block:

$Q_i(W_n; W_1) = n P_i(W_1) - P_i(W_n) = n P(W_1) - P(W_n) + \text{Noise} = Q(W_n; W_1) + \text{Noise}$

= will be fluctuating around the true $Q(W_n; W_1)$ due to noise

Ensemble average of $Q_i(W_n; W_1)$ ====> Noise Effect will be reduced

====> $P(W_n)$ = Phase at W_n can be better estimated

- Amplitude Information Recovery

$HC^2(W_n; W_1)$ = Hypercoherence Square = Percentage of power at W_n which is correlated with the fundamental frequency component.

====> $S_{xx}(W_n) HC^2(W_n; W_1)$ ====> Amplitude at W_n (A_n) can be estimated

$x(t) = \sum_{n=1}^2 A_n \cos[W_n t + P(W_n)]$ can be recovered and enhanced

LIMITATION OF HYPER-COHERENCE

$$Q(W_n; W_1) = n P(W_1) - P(W_n)$$

- The noise presented in $P(W_1)$ will be enlarged by n times.

When n is large, this noise component will be expanded over the $-\pi$ to π cycle, and folded back onto this $-\pi$ to π cycle.

==> smear the phase coherence.

- (1) n should not be too large. (LE 5 for typical SSME data)
- (2) Choose fundamental component with good SNR

GENERALIZED HYPER-COHERENCE (GHC)

-- Frequency Combination Requirement:

{	Bispectrum	--> (W1, W2, W1+W2 or W1-W2)
	Trispectrum	--> (W1, W2, W3, W1+W2+W3)
	Hyper-Coherence	--> (W1, N * W1) N = Integer
	????????	--> (W1, W2) Arbitrary Frequency Pair

-- 4KHz Example:

----> Components at (4KHz, *, N, 4N) do not satisfy any of the above frequency combination requirements.

GHC: Identify the correlation between two spectral components at arbitrary frequencies (W1, W2) in the sense of frequency lock-in (Frequency synchronous).

- Gear Box With Non-Integer Gear Ratio (R)

Gear#1 (N1-Tooth)

Gear#2 (N2-Tooth)

==> Gear Ratio $R = N1/N2$

ASSUMPTION: Perfect Gear Mesh (No Broken Or Worn Gear-Tooth)

- If Key-Phasor A goes through one cycle of rotation with angular displacement $a(t)$, then Key-Phasor B will finish R cycle of rotation with angular displacement $R*a(t)$
- The angular displacement $a(t)$ can be modeled as:

$$a(t) = \begin{cases} W1 t & \text{for pure harmonic motion (sine wave)} \\ W1 t + p(t) & \text{for motion with slowly phase drifting } p(t) \end{cases}$$

$$\begin{cases} \text{Gear\#1} \Rightarrow \cos[a(t)] = \cos[W1 t + p(t)] \\ \text{Gear\#2} \Rightarrow \cos[R*a(t)] = \cos[R*W1 t + R*p(t)] \end{cases}$$

- If Gear Ratio R is an integer: (R=n)

Hyper-Coherence \Rightarrow Compound Phase $Q(W_n, W_1) = n P(W_1) - P(W_n)$

$$\text{FFT} \Rightarrow \begin{cases} P(W_1) = p(t) + k_1(2\pi) \\ P(W_n) = n p(t) + k_2(2\pi) \end{cases}$$

$$\begin{aligned} \Rightarrow Q(W_n, W_1) &= [n p(t) + n k_1(2\pi)] - [n p(t) + k_2(2\pi)] \\ &= \underline{n k_1(2\pi) - k_2(2\pi)} = \text{constant phase} \end{aligned}$$

- If Gear Ratio R is not an integer: (R=R)

$$\text{FFT} \Rightarrow \begin{cases} P(W_1) = p(t) + k_1(2\pi) \\ P(W_R) = R p(t) + k_2(2\pi) \end{cases}$$

$$\Rightarrow Q(W_R, W_1) = \underline{R k_1(2\pi) - k_2(2\pi)} = \text{ambiguous phase (not unique)}$$

- GHC {
 - . use the RATE OF CHANGE OF PHASE (INSTANTANEOUS FREQUENCY)
 - . avoid the ambiguity of arbitrary integer multiple of 2π
 - . Frequency Synchronous: $p(t) = R p(t)$

NARROW-BAND RANDOM -- $x(t) = A(t) \cos[\omega_c t + p(t)]$

Instantaneous Amplitude -- $A(t)$

Instantaneous Frequency -- $\omega_c + \frac{d p(t)}{dt} = \omega_c + \omega_i(t)$

--> Intelligence $\omega_i(t)$ is Frequency Modulated in $x(t)$

SPECTRUM ESTIMATION

(1) FFT (DIRECT) METHOD

$$Xw(f) = \int_{-T/2}^{T/2} w(t) x(t) e^{-j2\pi ft} dt = X(f) * W(f)$$

$$\hat{S}(f) = |Xw(f)|^2 = |X(f) * W(f)|^2$$

STATISTICS:

$$\begin{cases} \text{Mean}[\hat{S}(f|T)] = E[\hat{S}(f|T)] = \int S(v) W(f-v) W^*(f-v) dv \\ \text{Cov}[\hat{S}(f_1|T)] = E[\hat{S}(f_1|T) \hat{S}(f_2|T)] \\ \quad = \left| \int S(v) W(f_1-v) W^*(f_2-v) dv \right|^2 \end{cases}$$

(2) BLACKMAN-TURKEY (INDIRECT) METHOD

$$\hat{R}(\tau|T) = \frac{1}{T} \int_{-T/2+\tau}^{T/2} x(t) x(t-\tau) dt$$

$$\hat{S}(f|T) = \int_{-T/2}^{T/2} w(\tau) \hat{R}(\tau|T) e^{-j2\pi f\tau} d\tau$$

STATISTICS:

$$\begin{cases} \text{Mean}[\hat{S}(f|T)] = E[\hat{S}(f|T)] = \int S(v) W(f-v) dv \\ \text{Cov}[\hat{S}(f_1|T)] = E[\hat{S}(f_1|T) \hat{S}(f_2|T)] \\ \quad = \frac{1}{T} \int S(v) [W(f_1-v) W^*(f_2-v) + W(f_1-v) W(f_2+v)] dv \end{cases}$$

Maximum Entropy Method (MEM) of Spectral Analysis (by J.P. Burg)

Entropy: a measure of average information content in a data set

(1) Discrete Random variable:

- . A communication system transmits M different messages m_1, m_2, \dots with probabilities of occurrence P_1, P_2, \dots respectively. Suppose that, during a long period of time, a total sequence of messages L has been generated. Then we would expect to find $L \cdot P_1$ messages of m_1 , $L \cdot P_2$ messages of m_2, \dots and so on.
- . The occurrence of a rare event contains more valuable information.
==> The value (weight) of each message is inversely proportional to its probability of occurrence.
==> total information in such a sequence can be defined as:

$$I = L P_1 \log(1/P_1) + L P_2 \log(1/P_2) + \dots = L \sum_{k=1} P_k \log(1/P_k)$$

Entropy (H) = The average information per message

$$H = I/L = \sum_{k=1} P_k \log(1/P_k)$$

(2) Continuous Random variable:

$$\text{Entropy } H = \int p(x) \log[1/p(x)] dx$$

$p(x)$ = joint p.d.f. of time series $\{x_1, x_2, x_3, \dots, x_n\}$

- if $\{x_1, x_2, x_3, \dots, x_n\}$ is Gaussian:

$$p(x) = \frac{1}{[(2\pi)^n \det(C_x)]^{1/2}} \exp\left[-\frac{1}{2}(x-\mu)^T C_x^{-1}(x-\mu)\right]$$

where C_x = covariance matrix; $C_{ij} = E[(x_i - \mu_1)(x_j - \mu_1)]$

$$\text{----> } H = 0.5 \log[\det(C_x)]$$

- if $\{x_1, x_2, x_3, \dots, x_n\}$ is zero-mean Gaussian:

$C_x = R_x$ = auto-correlation matrix; $R_{ij} = E[x_i x_j]$

$$\text{----> } H = 0.5 \log[\det(R_x)]$$

- From the relationship between $R_x(T)$ and $S_x(f)$

$$\text{----> } H = 0.5 \log(2B) + 1/(4B) \int \log[S_x(f)] df$$

MEM SPECTRUM ESTIMATION

Problem:

given measured $R(m)$, $m=1, M$, wish to find $\hat{R}_x(m)$ and $\hat{S}_x(f)$

such that:

- $$\begin{cases} (1) \text{ Entropy is maximized: } \frac{dH}{dR(m)} = 0 & \text{for } |m| > M \\ (2) \text{ Constrain: } \hat{R}(m) = R(m) & \text{for } |m| < M \end{cases}$$

Where $\hat{R}_x(m) \xrightarrow{\text{FFT}} \hat{S}_x(f)$

Result:

$$\hat{R}_x(m) = \sum_{n=1}^M A(n) \hat{R}(m-n)$$

$$\hat{S}_x(f) = \frac{2 \text{ PE}}{f_s \left| 1 - \sum_{m=1}^M A(m) \exp[-j2\pi m f / f_s] \right|^2}$$

. Coefficients $A(n)$ & PE can be obtained by solving

Wiener-Levinson equation:

$$\begin{bmatrix} R(0) & R(1) & R(2) & \dots & R(M) \\ R(1) & R(0) & R(1) & \dots & R(M-1) \\ R(2) & R(1) & R(0) & \dots & R(M-2) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ R(M) & R(M-1) & R(M-2) & \dots & R(0) \end{bmatrix} \begin{bmatrix} 1 \\ -A(1) \\ -A(2) \\ \vdots \\ -A(M) \end{bmatrix} = \begin{bmatrix} \text{PE} \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

. Levinson-Durbin Recursive Algorithm for Toeplitz matrix

AUTO-REGRESSIVE (AR) MODEL (by Van den Bos)

- AR Model: $x(n) = \sum_{m=1}^M A(m) x(n-m) + e(n) \quad n=1, M$

=> current data $x(n)$ can be predicted from past data $x(n-m)$ $m=1, M$
with prediction error $e(n)$ representing white noise

white noise has no memory ==> un-predictable

- Whitening Filter: $x(n) - \sum_{m=1}^M A(m) x(n-m) = e(n)$

=> $x(n) * h(n) = e(n)$; where: $h(0)=1, h(m)=-A(m)$

$x(n) \text{ ----> } \boxed{\begin{array}{c} \text{Whitening filter} \\ h(n), H(f) \end{array}} \text{ -----> } e(n) = \text{white noise} \\ \text{(Prediction error)}$

=> $S_e(f) = S_x(f) | H(f) |^2$

=> $S_x(f) = S_e(f) / | H(f) |^2$

Where : $\begin{cases} S_e(f) = 2 \text{ PE} / f_s \\ H(f) = 1 - \sum_{m=1}^M A(m) \exp[-j2\pi m f / f_s] \end{cases}$

====> $S_x(f) = \frac{2 \text{ PE}}{f_s | 1 - \sum_{m=1}^M A(m) \exp[-j2\pi m f / f_s] |^2}$

LEAST SQUARE ESTIMATION OF AR COEFFICIENTS A(m)

Problem:

given signal Model (AR): $x(n) = \sum_{m=1}^M A(m) x(n-m) + e(n) \quad n=1, M$

wish to find A(m) such that the expect value of $e(t)$ is minimized

$$PE = E [e(n)^2] = E [\{ x(n) - \sum_{m=1}^M A(m) x(n-m) \}^2]$$

$$(1) \quad d PE / d A(k) = 0 \quad \text{for } k=1, M$$

$$\begin{aligned} d PE / d A(k) &= - E [\{ x(n) - \sum_{m=1}^M A(m) x(n-m) \} x(n-k)] \\ &= - R(k) + \sum_{m=1}^M A(m) R(m-k) = 0 \end{aligned}$$

$$\Rightarrow \sum_{m=1}^M A(m) R(m-k) = R(k) \quad k=1, M \quad (\text{Yule-Walker equation})$$

$$\begin{bmatrix} R(0) & R(1) & R(2) & \dots & R(M-1) \\ R(1) & R(0) & R(1) & \dots & R(M-2) \\ R(2) & R(1) & R(0) & \dots & R(M-3) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ R(M-1) & R(M-2) & R(M-3) & \dots & R(0) \end{bmatrix} \begin{Bmatrix} A(1) \\ A(2) \\ A(3) \\ \vdots \\ A(M) \end{Bmatrix} = \begin{Bmatrix} R(1) \\ R(2) \\ R(3) \\ \vdots \\ R(M) \end{Bmatrix}$$

$$\begin{aligned} (2) \quad PE_{\min} &= E [\{ x(n) - \sum_{m=1}^M A(m) x(n-m) \} \{ x(n) - \sum_{k=1}^M A(k) x(n-k) \}] \\ &= E [\{ x(n) - \sum_{m=1}^M A(m) x(n-m) \} x(n)] = R(0) - \sum_{m=1}^M A(m) R(m) \end{aligned}$$

(3) Combine (1) and (2) \Rightarrow Wiener-Levinson equation:

$$\begin{bmatrix} R(0) & R(1) & R(2) & \dots & R(M) \\ R(1) & R(0) & R(1) & \dots & R(M-1) \\ R(2) & R(1) & R(0) & \dots & R(M-2) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ R(M) & R(M-1) & R(M-2) & \dots & R(0) \end{bmatrix} \begin{Bmatrix} 1 \\ -A(1) \\ -A(2) \\ \vdots \\ -A(M) \end{Bmatrix} = \begin{Bmatrix} PE_{\min} \\ 0 \\ 0 \\ \vdots \\ 0 \end{Bmatrix}$$

Conclusion:

\Rightarrow MEM-PSD is identical to AR-PSD

. MEM: Extending R(t) such that its entropy is maximized

. AR : Assuming AR model, minimizing its prediction error

FIGURE 4-50. COMPARISON BETWEEN FFT AND MEM SPECTRUM FOR LIMITED SAMPLE SIZE

(a) Raw data (1024 samples)
 (b) original a.c.f $R(t)$ from 1024 data samples
 (c) MEM extended $R(t)$

WIENER FILTER (by N. Wiener)

EXAMPLE:

- . wish to study the vibration response of the generator $s(t)$.
- . measurement $x(t)$ at the generator will be corrupted by the background noise $n(t)$ from the main engine
- . $n(t)$ is transmitted from the engine room to the pilot house through a unknown linear transfer function $H(f)$
- . Noise Cancellation --
 - . take additional measurement $y(t)$ (reference signal)
 - . estimate of $h(t)$.
 - . predict background noise $n(t)$ ($N(t) = y(t) * h(t)$)
 - . noise in the primary signal can be canceled

WIENER FILTER:

- Assumption:

1. $s(t)$ and $y(t)$ are independent
2. $y(t)$ and $n(t)$ are linearly correlated; $n(t) = y(t) * h(t)$
3. all signal are stationary
4. $H(f)$ is linear time invariant (LTI) system

- Wish to estimate I.R.F $h(t)$:

Prediction $\hat{n}(t) = y(t) * \hat{h}(t)$ = estimation of $n(t)$

Prediction error $e(t) = x(t) - \hat{n}(t)$ = estimation of $s(t)$

LEAST SQUARE ESTIMATION:

--> Find $h(t)$ such that $PE = E [|e(t)|^2]$ is minimized

$$PE = E [|e(t)|^2] = E [\{ x(t) - y(t) * h(t) \}^2]$$

Minimize PE with respect to $h(t)$

. discrete time, matrix form:

$$PE = R_{xx}(0) - 2 \mathbf{h}^T R_{xy} + \mathbf{h}^T R_{yy} \mathbf{h}$$

$$\frac{d PE}{d \mathbf{h}} = 0 \implies R_{yy} \mathbf{h} = R_{xy} \quad \text{Wiener-Hopf Equation}$$

$$\begin{bmatrix} R_{yy}(0) & R_{yy}(1) & R_{yy}(2) & \dots & R_{yy}(M-1) \\ R_{yy}(1) & R_{yy}(0) & R_{yy}(1) & \dots & R_{yy}(M-2) \\ R_{yy}(2) & R_{yy}(1) & R_{yy}(0) & \dots & R_{yy}(M-3) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ R_{yy}(M-1) & R_{yy}(M-2) & R_{yy}(M-3) & \dots & R_{yy}(0) \end{bmatrix} \begin{bmatrix} h(1) \\ h(2) \\ h(3) \\ \vdots \\ h(M) \end{bmatrix} = \begin{bmatrix} R_{xy}(0) \\ R_{xy}(1) \\ R_{xy}(2) \\ \vdots \\ R_{xy}(M-1) \end{bmatrix}$$

-----> optimal $h(t)$

predict background noise $\hat{n}(t)$

perform noise cancellation $s(t) = x(t) - \hat{n}(t)$

Disadvantage:

1. signal must be stationary
2. system must be time invariant
3. need block of data to calculate $h(t)$

--> difficult to perform on-line real-time processing

-----> Adaptive Filter

FINITE IMPULSE RESPONSE (FIR) ADAPTIVE FILTER

$$\text{Prediction Error } PE(t) = \sum_{s=0}^t q^{t-s} e(s)$$

q = forgetting factor

- update filter coeff. $h(t)$ at every new data point:
at next time step $t+1$: $h(t+1) = h(t) + \text{correction term}$
 - estimate new filter coeff. $h(t+1)$ by modifying the old filter coeff $h(t)$ with a correction term such that the new prediction error $PE(t+1)$ is minimized
 - Memory can be introduced into the Prediction Error $PE(t)$ by putting more weight on recent data and less weight on old data
 - Adjustable weighting : $\begin{cases} \text{when } q=1, & \text{infinite memory} \\ \text{when } q<1, & \text{exponential weighting} \end{cases}$
- ==> non-stationary data and time-varying system

(A) LEAST SQUARE ESTIMATION

Define:

$$x(n) = [x(0) \ x(1) \ \dots \ x(n-1) \ x(n)]^T$$

$$y(n) = [y(0) \ y(1) \ \dots \ y(n-1) \ y(n)]^T$$

$$e(n) = [e(0) \ e(1) \ \dots \ e(n-1) \ e(n)]^T$$

$$H(n) = [h_1 \ h_2 \ h_3 \ \dots \ h_N]$$

$$Q = \text{Diag}[q^{*n} \ q^{*(n-1)} \ \dots \ q^{*2} \ q \ 1]$$

$$Y(n) = \begin{bmatrix} 0 & 0 & 0 & 0 & \cdot & \cdot \\ y(0) & 0 & 0 & 0 & \cdot & \cdot \\ y(1) & y(0) & 0 & 0 & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ y(n-1) & \dots & \dots & \dots & \dots & y(n-N) \end{bmatrix}$$

$$\text{Prediction Error } PE(n) = \sum_{s=0}^n q^{n-s} e(s)^2$$

$$PE(n) = e(n)^T Q(n) e(n) \quad \text{where: } e(n) = x(n) - Y(n) H(n)$$

$$PE(n) = x(n)^T Q x(n) - 2 H(n)^T Y(n)^T Q(n) x(n) + H(n)^T Y(n)^T Q(n) Y(n) H(n)$$

$$\frac{d PE(n)}{d H(n)} = 0 \implies H(n) = [Y(n)^T Q(n) Y(n)]^{-1} Y(n)^T Q(n) x(n)$$

- This equation estimates the filter coefficients at time step n from the entire past data. It provides the basis for the adaptive filtering problem:

At next time step n+1, adaptive filter updates the filter coefficients through a recursive relationship between H(n) and H(n+1), which can be derived from this equation.

RECURSIVE LEAST SQUARE (RLS) ADAPTIVE ALGORITHM

$$\text{Least Square Est.} \Rightarrow H(n) = \underline{\underline{[Y(n)^T Q(n) Y(n)]^{-1} Y(n)^T Q(n) x(n)}}$$

$$\text{Define } P(n) = [Y(n)^T Q(n) Y(n)]^{-1}$$

$$\left\{ \begin{array}{l} \text{at time step } n: \quad H(n) = P(n) Y(n)^T Q(n) x(n) \\ \quad \quad \quad \Downarrow \\ \text{at time step } n+1: \quad H(n+1) = P(n+1) Y(n+1)^T Q(n+1) x(n+1) \end{array} \right.$$

From Matrix Partition, find recursive relationship between $P(n)$ and $P(n+1)$ as:

$$P(n+1) = \{ P(n) - P(n) y(n+1) [q + y(n+1)^T P(n) y(n+1)]^{-1} y(n+1)^T P(n) \} / q$$

====> recursive relationship between $H(n)$ and $H(n+1)$:

$$H(n+1) = H(n) + P(n+1) y(n+1) [x(n+1) - y(n+1)^T H(n)] \dots\dots(1)$$

Adaptive Procedure:

- . at time step n , only coefficients $H(n)$ and $P(n)$ are stored
- . at time step $n+1$ with new observations $x(n+1)$ and $y(n+1)$
 - Prediction: $\hat{x}(n+1) = y(n+1)^T H(n)$
 - Prediction error: $e(n+1) = x(n+1) - \hat{x}(n+1)$
 - update $P(n+1)$ from $P(n)$ and new observation $x(n+1)$ & $y(n+1)$
 - update $H(n+1)$ from $H(n)$, $P(n+1)$, $x(n+1)$ & $y(n+1)$
- . $H(n+1)$ updated from $H(n)$ is identical to the least square estimation from the entire past data ==> exact adaptation
- . $P(n)$ is $N \times N$ matrix. N = filter order
- ====> large computation and storage requirement

Equation (1): $H(n+1) = H(n) + P(n+1) y(n+1) [x(n+1) - y(n+1) H(n)]$

Prediction: $\hat{x}(n+1) = y(n+1)^T H(n)$

Prediction error: $e(n+1) = x(n+1) - \hat{x}(n+1)$

Define Kalman gain vector $K(n+1) = P(n+1) y(n+1)$

Equation (1) becomes: $H(n+1) = H(n) + e(n+1) K(n+1) \dots\dots(2)$

correction vector = $e(n+1) K(n+1)$:

- Prediction error $e(n+1)$ \implies the correction step size is proportional to $e(n+1)$
- Kalman gain vector $K(n+1)$ \implies the correction step direction

Fast Kalman Algorithm:

$$H(n+1) = H(n) + e(n+1) K(n+1)$$

recursive relationship to update $K(n+1)$ from $K(n)$ exactly

Widrow's LMS Adaptive Algorithm:

- The Steepest Decent optimization method:

wish to search the minimal location of PE w.r.t. to H ,

searching method: $H(n+1) = H(n) - s \text{ GRAD}$

where: $\text{GRAD} = \text{Gradient Vector} = d \text{ PE} / d H$

s = searching step size (scalar)

$$\text{GRAD} = \frac{d \text{ PE}}{d H} = \frac{d E[e(n)^2]}{d H}$$

$$\text{GRAD} = \frac{d [e(n)^2]}{d H(n)} = 2 e(n) \frac{d e(n)}{d H(n)}$$

where $e(n) = x(n) - y(n) H(n) \implies d e(n) / d H(n) = -y(n)$

$$\implies \text{GRAD} = -2 e(n) y(n)$$

Widrow's algorithm: $H(n+1) = H(n) + 2 \mu e(n) y(n) \dots\dots(3)$

μ = parameter controls stability and rate of convergence

SIMULATION EXAMPLES FOR ADAPTIVE FILTER

$\text{tksin}(t)$ = Truncated Sine Wave (Amp=1, 80% truncation)

$\text{gwn}(t)$ = Gaussian White Noise (variance =1)

$\text{fgwn}(t)$ = Filtered Gaussian White Noise = $\text{gwn}(t) * h(t)$

where: $h(t) = [1, 3, 5, 7, 9, 7, 5, 3, 1, 1]^T$

$\text{ch1}(t) = \text{tksin}(t) + 10 \text{ gwn}(t)$

$\text{ch2}(t) = \text{tksin}(t) + \text{fgwn}(t)$

$\text{ch3}(t) = \text{tksin}(t) + 10 \text{ fgwn}(t)$

$\text{ch4}(t) = \text{gwn}(t)$

ROTARY SPECTRUM ANALYSIS (C.N. Mooers)

. Linear Cross Spectrum/Coherence:

- To describe certain common or joint linear properties between two different random processes.

$$\text{---> } S_{xx}(w), S_{yy}(w), S_{xy}(w), Q_{xy}(w)$$

. Linear Rotary Spectrum/Coherence:

- To describe certain common or joint linear properties between two different random vectors.

$$\text{---> Complex Random Vectors } \begin{cases} z_1(t) = x_1(t) + j y_1(t) \\ z_2(t) = x_2(t) + j y_2(t) \end{cases}$$

- At each frequency, each random vector can be decomposed into two rotational circular motions, each with its own amplitude and phase. The counterclockwise (CCW) components correspond to motions at positive frequencies, and the clockwise (CW) components correspond to motions at negative frequencies.

ROTARY AUTO-SPECTRUM

- At frequency ω_0 , random vector $z(t) = x(t) + j y(t)$ represents an elliptic motion:

$$z(t) = X \cos(\omega_0 t + P_x) + j Y \cos(\omega_0 t + P_y)$$

Trigonometric Identity

$$z(t) = [A \cos(\omega_0 t + P_a) + B \cos(\omega_0 t + P_b)] + j [A \sin(\omega_0 t + P_a) - B \sin(\omega_0 t + P_b)]$$

Polar Format

$$z(t) = A e^{+j[\omega_0 t + P_a]} + B e^{-j[\omega_0 t + P_b]}$$

C.C.W Component
C.W component

Fourier Transform

$$Z(\omega) = [A \exp(j P_a)] \delta(\omega - \omega_0) + [B \exp(-j P_b)] \delta(\omega + \omega_0)$$

C.C.W Component at $\omega = +\omega_0$
C.W component at $\omega = -\omega_0$

- At each frequency ω , the elliptical motion is decomposed into two C.C.W. and C.W. circular motions.

$$\begin{cases} \text{CCW Motion:} & \text{Frequency} = +\omega_0 & \text{Amplitude} = A & \text{Phase} = P_a \\ \text{CW Motion:} & \text{Frequency} = -\omega_0 & \text{Amplitude} = B & \text{Phase} = P_b \end{cases}$$

- Inner Auto-Spectrum $S(\omega) = E[Z(\omega) Z(\omega)]$

==> $S(\omega)$ measures the power distribution of the C.W.

and C.C.W. components at each frequency.

- Outer Auto-Spectrum $T(\omega) = E[Z(-\omega) Z(\omega)]$

==> $T(\omega)$ measures the amount of correlated power between the C.W. and C.C.W. components at each frequency.

- Outer Auto-Coherence $t(\omega) = E[Z(-\omega) Z(\omega)] / [S(-\omega) S(\omega)]$

==> $t(\omega)$ measures the coherence between the C.W. and C.C.W. components at each frequency. It indicates the degree of stability of the elliptical motion.

ROTARY CROSS-SPECTRUM

- At frequency ω_0 , $z_1(t)$ & $z_2(t)$ represent two elliptical motions

$$\begin{cases} z_1(t) = A_1 e^{+j[\omega_0 t + Pa_1]} + B_1 e^{-j[\omega_0 t + Pb_1]} \\ z_2(t) = A_2 e^{+j[\omega_0 t + Pa_2]} + B_2 e^{-j[\omega_0 t + Pb_2]} \end{cases}$$

$$\begin{cases} Z_1(\omega) = [A_1 \exp(j Pa_1)] \delta(\omega - \omega_0) + [B_1 \exp(-j Pb_1)] \delta(\omega + \omega_0) \\ Z_2(\omega) = [A_2 \exp(j Pa_2)] \delta(\omega - \omega_0) + [B_2 \exp(-j Pb_2)] \delta(\omega + \omega_0) \end{cases}$$

- Inner Cross-Spectrum $S_{12}(\omega) = E[Z_1(\omega) Z_2^*(\omega)]$

=> $S_{12}(\omega)$ measures the amount of correlated power between $z_1(t)$ and $z_2(t)$ at the same direction (both CW and CCW)

- Inner Cross-Coherence $r_{12}(\omega) = S_{12}(\omega) / [S_{11}(\omega) S_{22}(\omega)]$

=> $r_{12}(\omega)$ measures the coherence between $z_1(t)$ and $z_2(t)$ at the same direction (both CW and CCW)

$z_1(t)$		$z_2(t)$
CW	<----->	CW
CCW	<----->	CCW

- Outer Cross-Spectrum $T_{12}(\omega) = E[Z_1(-\omega) Z_2(\omega)]$

=> $T_{12}(\omega)$ measures the amount of correlated power between $z_1(t)$ and $z_2(t)$ at the opposite direction (CW/CCW , CCW/CW)

- Outer Cross-Coherence $q_{12}(\omega) = T_{12}(\omega) / [S_{11}(-\omega) S_{22}(\omega)]$

=> $q_{12}(\omega)$ measures the coherence between $z_1(t)$ and $z_2(t)$ at the opposite direction (CW/CCW , CCW/CW)

$z_1(t)$		$z_2(t)$
CW	<----->	CCW
CCW	<----->	CW

SIMULATION EXAMPLE FOR ROTARY SPECTRUM

- Let $z_1(t)$ and $z_2(t)$ represent the vibration response random vectors near each end of a rotating shaft. If a bending mode of the shaft at natural frequency 1000 Hz is excited to generate a C.C.W. rotational motion. Assuming that, at this same frequency, forces from some other independent sources at each end of the shaft also generate a C.W. rotational motion.

CORRELATED CCW MOTION INDEPENDENT CW MOTION

$$z_1(t) = A_1 e^{+j[\omega t + Pa_1(t)]} + B_1 e^{-j[\omega t + Pb_1(t)]}$$

$$z_2(t) = A_2 e^{+j[\omega t + Pa_2(t)]} + B_2 e^{-j[\omega t + Pb_2(t)]}$$

where: $A_1 = A_2 = 1$ $B_1 = B_2 = 10$ $\omega = 1000 \text{ Hz}$

$$Pa_2(t) = Pa_1(t) + \text{constant phase lag}$$

$Pa_1(t)$, $Pb_1(t)$, and $Pb_2(t)$ are independent random drifting phases.

--> wish to identify the correlation of the CCW motion between $z_1(t)$ and $z_2(t)$.

- Since the amplitude of the independent CW motion is 10 times larger than the amplitude of the correlated CCW motion.

Therefore, the linear cross-coherence: $Q_{x_1 x_2}(\omega)$, $Q_{y_1 y_2}(\omega)$,

$Q_{x_1 y_2}(\omega)$, $Q_{x_2 y_1}(\omega)$ would not be able to identify the correlation of the CCW motion between $z_1(t)$ and $z_2(t)$.

PSD of $x1(t)$, $y1(t)$ $z1(t) = x1(t) + j y1(t)$

PSD of $x2(t)$, $y2(t)$ $z2(t) = x2(t) + j y2(t)$

Linear Cross-Coherence for (x1,y1) (x2,y2)

Linear Cross-Coherence for (x1,x2) (y1,y2) (x1,y2) (x2,y1)

- (1) S11(w) = Inner Autot-Rotary-Spectrum for Z1(t)
- (2) S22(w) = Inner Autot-Rotary-Spectrum for Z2(t)

- (1) MU1(w) = Stability of Ellipse for Z1(t)
- (2) MU2(w) = Stability of Ellipse for Z2(t)

- (1) COHI(w) = Inner-Cross-Coherence Between Z1(t) & Z2(t)
- (2) COHO(w) = Outer-Cross-Coherence Between Z1(t) & Z2(t)

FREQUENCY WAVENUMBER SPECTRUM

. Single channel signal:

time domain <===> frequency domain
 $y(t) = A \cos(\omega t + p)$ <===> $Y(\omega) = A \exp[jp]$

. Array signal:

time domain <===> frequency domain
 spatial domain <===> wavenumber domain
 $y(t, x) = A \cos(\omega t + kx + p)$ <===> $Y(\omega, k) = A \exp[jp]$

. Conventional Methods:

- Two Dimensional FFT (Periodogram):
- Blackman/Turkey (cross-correlation) :

. Parametric Methods:

- MEM (Auto-Regressive) Model:
- LMS & MLM Adaptive array processing Algorithm:

- Leftward Traveling wave:

$$y(t,x) = A \cos(\omega_0 t + k_0 x + p)$$

=> Positive Wavenumber

- Rightward Traveling wave:

$$y(t,x) = A \cos(\omega_0 t - k_0 x + p)$$

=> Negative Wavenumber

- Standing wave:

$$\begin{aligned} y(t,x) &= A \cos(\omega_0 t + k_0 x + p) \\ &\quad + A \cos(\omega_0 t - k_0 x + p) \\ &= 2A \cos(k_0 x) \cos(\omega_0 t + p) \end{aligned}$$

=> Positive & Negative Wavenumber

SIMULATION EXAMPLE:

$$y(t,x) = \sum_{j=1}^{64} A_j \cos(\omega_j t + k_j x + p_j) \quad j=1,2,3,\dots,64$$

(3) Narrow-Band Random

$$\text{COS}[\text{W(t)t+p}]$$

$$\text{PDA}(w) = E [P(w) - WT]$$

Where $P(w)$ = time Realigned Phase from $X(W)$
 WT = Phase of Reference Sine Wave at time T

CHIRP-Z TRANSFORM

. Z-Transform (ZT):

$$X(z) = \sum_{n=-\infty}^{\infty} x(n) z^{-n}$$

- z is a complex variable.
- $X(z)$ is a continuous function in z -plane

. Fourier Transform (FT): evaluate ZT $X(z)$ on the unit circle.

$$X(w) = \sum_{n=-\infty}^{\infty} x(n) [e^{jw}]^{-n}$$

- $z = \exp(jw)$ $w=0$ to 2π \implies Unit Circle (U.C.)
- $X(w)$ is a continuous function on the U.C. in z -plane

. Discrete Fourier Transform (DFT): evaluate FT $X(w)$ at N equally spaced points on the U.C.

$$X(k) = \sum_{n=-\infty}^{\infty} x(n) [e^{j 2\pi k/N}]^{-n}$$

- $z = \exp(j 2\pi k/N)$ $k=0, N$ \implies Frequency Interval = $2\pi/N$
- $X(k)$ is a discrete function on the U.C. in z -plane

. Fast Fourier Transform (FFT): An efficient algorithm to compute DFT $X(k)$

- . Wish to evaluate Z-Transform over a small portion on the unit circle (U.C.) with much larger # of sampling points

to evaluate Z-Transform on some other contour rather than the U.C.

\implies Chirp-Z Transform (CZT)

. CZT evaluates Z-Transform over a portion on a spiral contour

$$X(k) = \sum_{n=0}^{M-1} x(n) \left[A_0 e^{j\theta_0} W_0^{-k} e^{jk\phi_0} \right]^{-n} \quad k=0,1,\dots,M-1$$

A_0 and θ_0 are the starting amplitude and phase of the contour

ϕ_0 is the angular spacing sampled on the contour

W_0 controls the rate at which the contour spirals

$$\begin{cases} W_0 > 1 & \Rightarrow \text{contour spirals inward} \\ W_0 < 1 & \Rightarrow \text{contour spirals outward} \end{cases}$$

Fig. 6.32 Interpretation of Eq. (6.41) in terms of a linear system.

- Evaluation of CZT By Using FFT Algorithm

$$\text{CZT: } X(z_k) = \sum_{n=0}^{N-1} x(n) A^{-n} W^{nk}, \quad k = 0, 1, \dots, M-1$$

$$W = W_0 e^{-j\phi_0}$$

$$A = A_0 e^{j\theta_0}$$

Using the identity: $nk = \frac{1}{2}[n^2 + k^2 - (k-n)^2]$

$$X(z_k) = \sum_{n=0}^{N-1} x(n) A^{-n} W^{n^2/2} W^{k^2/2} W^{-(k-n)^2/2}$$

$$X(z_k) = W^{k^2/2} \sum_{n=0}^{N-1} x(n) A^{-n} W^{n^2/2} W^{-(k-n)^2/2}$$

$$g(n) = x(n) A^{-n} W^{n^2/2}$$

$$X(z_k) = W^{k^2/2} \sum_{n=0}^{N-1} g(n) W^{-(k-n)^2/2}, \quad k = 0, 1, \dots, M-1$$

↑
Convolution between $g(n)$ and $h(n) = W^{-n^2/2}$

-----> FFT Algorithm can be used to perform the convolution

COMPLEX TOPO -- COMPRESSED SSME VIBRATION DATA BASE

- . For each test: Sampling Frequency = 10KHz, Time period=500 sec.
20 Channels/Test, eg. HPFP, HPOP, LPFP, LPOP, PBP, WLD3, SPD...
Each channel: 1250 4K data block ==> 4K FFT ==> Complex Topo
Each FFT Peak: Amplitude, Phase, Frequency ==> Four-Byte Storage
If store 50 peaks/FFT ==> $20 \times 1025 \times 50 \times 4 = 4.1$ MB
For 600 tests: 600×4.1 MB = 2.46 GB of complex topo
- . For Raw FFT data: $600 \times 20 \times 500 \times 10240 \times 4 = 246$ GB storage
---> Compression Ratio = 246 GB : 2.46 GB = 100 : 1
- . Identify 10 segments of stationary period, and store PSD's.
Composite RMS time history tracking
---> Compression Ratio = 246 GB : 2.95 GB = 84 : 1

COMPACT DATA BASE IN A SINGLE 4-GB LASER DISC

- . Provides quick and efficient recall capabilities to extract information from past test data.
- . Major information is preserved with minimum storage requirement.
 - Frequency domain characteristics: Representative PSD's
 - Time-Frequency trending of different mechanical failure modes and/or any anomalous phenomena.

INFORMATION RECONSTRUCTION:

- . frequency/amplitude tracking for Sync, harmonics and anomalous frequency components.
- . test-to-test trend analysis
- . retrieve signature characteristics
 - linear cross-coherence and phase
 - auto-cross bi-coherence and tri-coherence analysis
 - hyper-coherence analysis
 - hyper-coherence filtering: periodic waveform recovery
 - orbit analysis: backward & forward rotational motion

SIGNATURE COMPARISON

- . Fast recall and comparison over large amount of history tests.
- . Automatic discrimination between nominal and anomalous signals.
- . Pattern classification - transform various signal pattern into vectors to construct a memory matrix.
- . Automated Pattern Mapping Algorithm - Associative Memory Mapping: a transformation in which a finite number of input pattern vectors is mapped into a given set of memory matrix.

IDENTIFY PROBABILITY DISTRIBUTIONS, STATISTICS OR CORRELATIONS

- . Relative Phase difference between Sync and its harmonics
 - Any fixed relationship? If not, what is the distribution?
- . Orbit direction at different PWL
 - Any fixed direction? If yes, exceptions ---> ?
- . Phase of Auto-Bicoherence Bxxx(18N, 12K ; star)
 - constant phase? If yes. It then represents a key signature.
- . Amplitude Distribution of Sync, Harmonics, Harmonics/Sync ratio

SUMMARY

- (1) High Order Cumulant Function and Cumulant Spectrum:
 - Theory of General N-th Order Nonlinear Spectral Analysis
- (2) Auto/Cross Bi-spectrum/Bi-coherence:
 - Quadratic Correlation Among Three Waves At (W_1 , W_2 , W_1+W_2)
- (3) Auto/Cross Tri-Spectrum/Tri-Coherence:
 - Cubic Correlation Among Four Waves At (W_1 , W_2 , W_3 , $W_1+W_2+W_3$)
 - Modulation Generated Side-Band Structure At (W_c-D , W_c , W_c+D)
- (4) Hyper-Coherence:
 - Harmonic Identification (W_r , $N*W_r$)
- (5) Hyper-Coherence filtering:
 - Periodic Waveform Enhancement
 - Orbit Plot
- (6) Generalized Hyper-Coherence:
 - Correlation Between Arbitrary Frequency Pair (W_1 , W_2)
 - Instantaneous Frequency
- (7) MEM Spectrum Estimator:
 - Prediction Auto-Correlation Function Beyond the Maximum Time Lag by Maximizing Its Entropy
- (8) AR Spectrum Estimator
 - Time Domain Signal Can Be Represented By An AR Model.
Estimate Its AR Coefficients and PSD by Minimizing Its Prediction Error.

(9) RLS FIR Adaptive Filter & Widrow's LMS Adaptive Filter:

- Predict Background Noise In The Primary Signal From a Correlated Reference Signal.

(10) Cepstrum Analysis:

- Convert Time Domain Convolution To Frequency Domain Multiplication, To Quefrency Addition.
- Deconvolution

(11) Rotary Spectrum:

- Decompose a Random Vector Into C.W. And C.C.W. Rotational Components.
- Identify Correlation Among Different Rotational Components.

(12) Wave Number Spectrum:

- Transform Time-Spatial Array Signal Into Its Frequency-Wavenumber Domain.
- Identify Left- & Right-ward Traveling Wave or Standing Wave.

(13) Phase Domain Average (PDA):

- Identify Discreteness Of A Spectral Component By Tracing The Variation Of Phase Drifting.
- Phase Estimation Through Chirp-Z Transform.

(14) Chirp-Z Transform:

- Evaluate Z-Transform Over A Portion On A Spiral Contour.

(15) Topo:

- Transform SSME Vibration Signal into a Compressed Topo Data Base To Provide An Equivalent Image-Pattern.
- Pattern Recognition For Signal Classification.
